#### Abstract

This paper analyzes the electrical behaviour of resistive opens as a function of its unpredictable resistance. It is demonstrated that the electrical behaviour depends on the value of the open resistance. It is also shown that, due to the memory effect detection of the open by a given vector Ti depends on all the vectors that have been applied to the circuit before Ti. An electrical analysis of this memory effect is presented.

## I. INTRODUCTION

Due to the complexity of IC technological process, many physical defects occur during the manufacturing of any system. The typical defects encountered in today technologies and modeled in yield simulators are the socalled spot defects that may cause shorts and/or opens at one or more of the different conductive levels of the devices. Test generation for any type of defect is obviously not feasible due to the huge amount of CPU time and memory size required. Instead, test generation relies on fault models that are supposed to both represent the defect behavior and allow easy generation of test vectors through ATPG and fault simulation. However, it is well-known that these fault models cover only partially the spectrum of real failures in today's integrated circuits. In particular, a special attention must be paid to defects that exhibit complex behavior not accurately represented by classical fault models and defects with a high probability of occurrence [15]. A number of research works have been conducted in the past years dealing with the electrical characterization and modeling of resistive opens [6-9]. Classically, it is considered that the connection is fully open, i.e. the following gates are completely disconnected and called 'floating gates'.

In this paper, we analyze the case where the following gates are still connected but through a degraded line exhibiting some resistance [10-17]. It is important to note that the value of this resistance is an unpredictable parameter of the defect. The electrical behavior of the defect obviously depends on this random parameter as well as its detection conditions. In order to optimize and guarantee the detection of such a defect, its electrical behavior has to be
analyzed as a function of this random parameter and optimal detection conditions must be derived.

The paper will be organized as follows. Section 2 gives the general definitions around resistive opens. In section 3 and 4 , the detection of the open is analyzed considering a sequence of 2 test vectors, then considering a sequence of $n$ test vectors. Starting from this analysis, section 5 proposes an electrical model for the memory effect of resistive opens. Finally, section 6 gives some concluding remarks.

## II. DEFINITION

In this section, an electrical analysis of the resistive open is conducted using a didactic circuit. Figure 1 gives an example of an extremely simple circuit where node $n_{4}$ is affected by a resistive open. This didactic circuit has 4 inputs $\left(I_{1}, I_{2}, I_{3}, I_{4}\right)$ and 2 outputs $\left(O_{1}, O_{2}\right)$. Note that we do not care for the logic function; we just need a simple example to conduct our electrical analysis. Obviously, the demonstrations given below can be extended to real cases.

Figure 1. A resistive open
From a static voltage test point of view (Boolean testing), it is well known that a resistive open cannot be detected because the faulty node always ends up reaching its correct logic value. On the contrary, resistive opens modify the timing behavior of the circuit, so they can be detected by a dynamic voltage test strategy (delay testing).

A SPICE simulation of the defect-free circuit $\left(R_{o p}=\right.$ $0 \Omega$ ) using a 180 nm technology is first performed. Analysis of the dynamic behavior requires to create some signal transitions on the circuit inputs and to propagate these transitions through the circuit. The initial state is given by vector $T_{0}=<I_{1}, I_{2}, I_{3}, I_{4}>=<0011>$ and the transition is created by vector $\left.T_{1}=<0111\right\rangle$. Only input $I_{2}$ switches from 0 to $V_{D D}$ at time $t_{0}=0$, creating the transition. This
transition propagates through the critical path including gates $1 / 2 / 3 / 4 / 5 / 7 / 8 / 9$ and output $O_{2}$ switches from 0 to $V_{D D}$ ． From this simulation，we consider that we can use a cycle time of about $T_{c l}=0.4 \mathrm{~ns}$ with a small but reasonable security margin．

Figure 2．Defect－free path（ $I_{2}$ to $O_{1}$ ）
We perform now another simulation of the fault free circuit（ $R_{o p}=0 \Omega$ ）illustrated in Figure 2 with two different vectors：$T_{0}=\langle 1010\rangle$ and $T_{1}=\langle 1110\rangle$ ．Input $I_{2}$ again switches from 0 to $V_{D D}$ but，in this case，the rising edge is propagated to output $O_{1}$ through gates $1 / 2 / 3 / 4 / 5 / 6$ ．The propagation of this rising edge allows to give the following definitions：
－$\quad T_{p b}$（Propagation Before the defect），
－$\quad T_{p a}$（ Propagation $\underline{\text { Affter the defect }), ~}$
－$\quad T_{s l}$（Slack Time of path $I 2 \rightarrow O 1$ ）．
The rising edge of input $I_{2}$ reaches the defect at time $T_{p b}$ $=0.135 \mathrm{~ns}$ ，which is considered equal to the sum of the different gate propagation delays：

$$
\begin{equation*}
T_{p b}=T_{d 1}+T_{d 2}+T_{d 3}+T_{d 4}=0.135 \mathrm{~ns} \tag{1}
\end{equation*}
$$

where $T_{d i}$ ：propagation delay of gate＇$i$＇．
In the above equation，each gate propagation delay $T_{d i}$ depends on：
－the node capacitance $C_{n i}$
－the strength of the driving gate $W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i}$
－the resistance $R_{n i}$ of line $n_{i}$（often neglected）．
Then the edge propagates from the defect to the output and reaches output $O_{1}$ in a period of time $T_{p a}=0.065 \mathrm{~ns}$ that depends on the propagation delay of gates $5 / 6$ ：

$$
\begin{equation*}
T_{p a}=T_{d 5}+T_{d 6}=0.065 \mathrm{~ns} \tag{2}
\end{equation*}
$$

Finally，output $O_{1}$ stays stable for a period of time $T_{s 1}=$ 0.2 ns before being latched，assuming some output register． Obviously，the following relation links the different times：

$$
\begin{equation*}
T_{c l}=T_{p b}+T_{p a}+T_{s l} \tag{3}
\end{equation*}
$$

## III．DETECTION WITH A 2－VECTOR SEQUENCE

$W_{\text {e }}$e consider now the faulty circuit，i．e．a non－zero resistance．The open resistance $R_{o p}$ is a random parameter of the defect and can not be predicted，but we can simulate different cases of resistance value．Figure 3．a gives an example of open where the value of the resistance is quite small：$R_{o p}=3 \mathrm{k} \Omega$ ．Here again，a sequence of 2 vectors creating a transition is applied：$T_{0}=<1010>$ and $T_{1}=$
$<1110\rangle$ ．Input $I_{2}$ switches and the rising edge is propagated to node $n_{4}$ ．It clearly appears that the signal at node $n_{4}$ is slowed down．An additional delay $T_{o p}=0.13 \mathrm{~ns}$ appears．But the size of the timing defect is still smaller than the slack time，a correct output value is latched in the output register and the circuit operates correctly：
$T_{p b}+T_{o p}(3 \mathrm{k} \Omega)+T_{p a}<T_{c l}$
Figure 3．b gives another example where the value of the open resistance is higher：$R_{o p}=7.5 \mathrm{k} \Omega$ ．In this latter case，the size of the timing defect is larger than the slack time and so the rising transition of output $O_{1}$ occurs after the end of the cycle time．A faulty output value is captured in the output register and the open can be detected：

$$
\begin{equation*}
T_{p b}+T_{o p}(7.5 \mathrm{k} \Omega)+T_{p a}>T_{c l} \tag{5}
\end{equation*}
$$

The above simple simulations demonstrate that detection of the open depends on its random resistance．In a more general way，the rising transition of a faulty node ni and therefore the additional delay $T_{o p}$ depend on：
－the node electrical parameters $R_{n i}, C_{n i}$
－the strength of the driving gate $W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i} \ldots$
－the defect random parameter $R_{o p}$
－the initial voltage $V_{0}$
$=>T_{o p}=F\left(R_{o p}, V_{0}, R_{n i}, C_{n i}, W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i}\right)$

a）Small resistance $R_{o p}=3 \mathrm{k} \Omega$

b）High resistance $R_{o p}=7.5 \mathrm{k} \Omega$
Figure 3．Dynamic behavior of a resistive open
From Figure 3，it is clear that an open with a small resistance（ $3 \mathrm{k} \Omega$ ）cannot be detected while an open with a large resistance $(7.5 \mathrm{k} \Omega)$ can be detected．

This means that a given resistive open can be detected by the 2 －vectors sequence $\left\{T_{0}, T_{1}\right\}$ if its unpredictable resistance $R_{o p}$ is larger than a critical resistance called
$R_{c}{ }^{\{T 0, T 1\}}$. In other words, we associate to the resistive open the Detection Interval $D I$ defined below:
$D I^{\{T 0, T 1\}}=\left[R_{c}^{\{70, T 1\}}, \infty\right]=[7.5 \mathrm{k} \Omega, \infty]$
The critical resistance is the resistance value such that the additional delay $T_{o p}$ is equal to the slack time:
$T_{o p}=T_{s 1}=T_{c l}-T_{p b}-T_{p a}$
In fact, the SPICE simulation of Figure 3.b corresponds to this critical resistance $R_{c}{ }^{\{70, T 1\}}=7.5 \mathrm{k} \Omega$. In other words, any open with a resistance larger than $7.5 \mathrm{k} \Omega$ can be detected by the 2 -vector sequence $\left\{T_{0}, T_{1}\right\}$. An open with a smaller resistance creates an additional delay which is too small to be detected.

## IV. DETECTION WITH AN N-VECTOR SEQUENCE

$\mathbf{N}_{\text {ow, we consider a more realistic situation where, starting }}$ from an initial state given by $T_{0}$, a complete test sequence of m vectors is applied to the circuit targeting different defects/faults:
Test sequence $=\left\{T_{0}, T_{1}, \ldots, T_{n-1}, T_{n}, \ldots, T_{m}\right\}$
In this sequence, we assume now that vector $T_{n}$ has been specifically generated to detect the resistive open on node $n_{4}$. Tn is such that the transitions created by the 2 vectors $\left\{T_{n-1}, T_{n}\right\}$ are able to detect the resistive open on node $n_{4}$. In other words, the pair $\left\{T_{n-1}, T_{n}\right\}$ creates a transition that passes through node $n_{4}$ and is propagated to an observable output.

It is important to note that the preceding vectors $\left\{T_{0}\right.$, $\left.T_{1}, \ldots, T_{n-1}\right\}$ may create some transitions of node $n_{4}$ but these transitions are not propagated to an output, i.e. the open is not detected before vector $T_{n}$. For detection of the resistive open, we consequently divide the sequence into 2 phases:

- The preparation phase corresponds to the application of the $n-1$ vectors $\left\{T_{1}, \ldots, T_{n-1}\right\}$ starting from the initial state $T_{0}$, i.e. when the open cannot be detected but the faulty node may switch.
- The detection phase corresponds to the application of vector $T_{n}$, i.e. when the faulty node switches and it is observable on the outputs.

As an example, for the resistive open of Figure 1, we consider the preparation phase made of the initial state $\left\{T_{0}\right\}$ and a sequence of 5 vectors $\left\{T_{1}, T_{2}, T_{3}, T_{4}, T_{5}\right\}$, and the detection phase made of vector $\left\{T_{6}\right\}$, i.e. the case where $n=$ 6. These vectors are given in Table 1.

Table 1: The simulated test sequence

| Phase | Vector | Cycle |  |  |  | 4 | Transition Polarity on $n 4$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | T0 | Initial State | 0 | 0 | 1 | 0 |  |
|  | T1 | \#1 | 0 | 1 | 1 | 0 | $+4$ |
|  | T2 | \#2 | 0 | 0 | 1 | 0 | - 2 |
|  | T3 | \#3 | 0 | 1 | 1 | 0 | + 4 |
|  | T4 | \#4 | 0 | 1 | 1 | 0 | $+5$ |
|  | T5 | \#5 | 0 | 0 | 1 | 0 | - |
| Detection | T6 | \#6 | 1 | 1 | 1 | 0 | $+4$ |

From the input vectors in Table 1, we deduce that:

- Inputs $I_{3}$ and $I_{4}$ are stable. $I_{3}$ is equal to 1 , which always enable propagation of the $I_{2}$ input transition through gate 3 along the 6 cycles. $I_{4}$ is equal to 0 preventing propagation through gate 7 and so output $O_{2}$ remains at 1 .
- Input $I_{1}$ is equal to 0 along the first 5 cycles (propagation phase) preventing propagation through gate 6 during the first 5 cycles. And so, the resistive open cannot be detected during the first 5 cycles. Then input $I_{1}$ switches to 1 in the sixth cycle allowing propagation through gate 6 and so enabling detection (detection phase).
- Input $I_{2}$, starting from 0 , successively switches to 1,0 , $1,1,0$ and 1 , creating different transitions in the circuit.

In this simple and didactic example, node n 4 is observable on output $O_{1}$ only during the $6^{\text {th }}$ cycle when $I_{1}=$ 1. Vector $T_{6}$ has obviously been generated on purpose, i.e. to detect a fault on node $n_{4}$ and so it makes node $n_{4}$ observable. The previous vectors $\left(T_{1}, \ldots, T_{5}\right)$ have been generated targeting some other faults.

## a) Preparation phase

We first analyze the preparation phase. As commented above, during the first 5 cycles node $n_{4}$ is not observable, but it may switch from 0 to 1 or from 1 to 0 according to the activity of the circuit induced by the input vectors. In other words, the successive input vectors may create successive transitions of node $n_{4}$. In the fault-free circuit node $n_{4}$ switches from Gnd to $V_{D D}$ and vice-versa, but in the faulty circuit the signal is degraded by the resistive open. Two cases may appear:

- If the resistance of the open is small, the signal is slowed down but it is still able to reach the Gnd and $V_{D D}$.
- If the resistance of the open is large enough, the signal is slowed down and it is not always able to reach the $V_{D D}$ and $G n d$ values as illustrated in Figure 4 with $R_{o p}=7.5 \mathrm{k} \Omega$.

Let us explain in detail the second case with the example of Figure 4. Input $I_{2}$ is initially equal to 0 (initial state $T_{0}$ ) and switches to $1\left(T_{1}\right)$ at time $t_{0}$. At time $t_{0}+T_{p b}$, the rising transition reaches the output of gate 4 and so the voltage $V(t)$ of node $n_{4}$ starts switching from $V_{0}=G n d$ to $V_{D D}$.

Due to the resistance $R_{o p}$ of the defect, the time required by $V(t)$ to reach $V_{D D}$ is much higher than the cycle time $T_{c l}$. At the end of the $1^{\text {st }}$ cycle, i.e. at time $\left(t_{0}+T_{c l}\right)$, input $I_{2}$ switches from 1 to $0\left(T_{2}\right)$ and this new transition reaches node $n_{4}$ at time $\left(t_{0}+T_{c l}+T_{p b}\right)$. This new transition interrupts the previous one even if node $n_{4}$ has not yet been able to reach $V_{D D}$. Consequently, we observe that, during the first cycle, node $n_{4}$ rises from $V_{0}=V\left(t_{0}+T_{p b}\right)=0 \mathrm{~V}$ to $V_{1}$ $=V\left(t_{0}+T_{c l}+T_{p b}\right)=1.26 \mathrm{~V}$.

Obviously, we can make the same demonstration for the second cycle where a new transition on node $n_{4}$ interrupts the previous one and the voltage on node $n_{4}$ falls from $V_{1}=V\left(t_{0}+T_{c l}+T_{p b}\right)$ to $V_{2}=V\left(t_{0}+2 T_{c l}+T_{p b}\right)$. In a similar way, the voltage rises from $V_{2}=V\left(t_{0}+2 T_{c l}+T_{p b}\right)$ to $V_{3}=V\left(t_{0}+3 T_{c l}+T_{p b}\right)$ during the third cycle, and so forth.

Figure 4．Dynamic behavior through a sequence
Table 2．Simulated successive intermediate voltages

| Vector | Intermediate <br> Voltages |
| :---: | :--- |
| Initial State | $\mathrm{V} 0=0 \mathrm{~V}$ |
| T 1 | $\mathrm{~V} 1=1.26 \mathrm{~V}$ |
| T 2 | $\mathrm{~V} 2=0.36 \mathrm{~V}$ |
| T 3 | $\mathrm{~V} 3=1.39 \mathrm{~V}$ |
| T4 | $\mathrm{V} 4=1.70 \mathrm{~V}$ |
| T5 | $\mathrm{V} 5=0.49 \mathrm{~V}$ |

So，we globally observe that the voltage on node $n_{4}$ does not simply switch between $G n d$ and $V_{D D}$ ．Instead，it rises and falls according to the input vectors and goes through a set of successive intermediate voltages $V_{0}, V_{1}, V_{2}$ ， $V_{3}, V_{4}, V_{5}$ whose values are given in Table 2.

Important is the fact that these successive voltages are more or less following the clock of the circuit．Indeed，they appear at a period of time $T_{p b}$ after the clock pulse．In the general case，the transition may use different path for different vectors and so，the different points will appear at different after the clock．Consequently，the periodicity may vary from vector to vector but not too much because the propagation paths before the defect $T_{p b i}$ are not varying too much．In addition，the transitions are always initiated by the circuit inputs that follow the circuit clock．And so the global period will correspond to the circuit clock frequency $T_{c l}$ ．

For the above reasons，we will say that the successive intermediate voltages exhibit a pseudo－period equals to the circuit clock $T_{c l}$ ．

Very important is also the fact that，for each vector $T_{j}$ ， the corresponding intermediate voltage $V_{j}$ on node $n_{i}$ depends on：
－the polarity of the transition
－the node electrical parameters $R_{n i}, C_{n i}$
－the strength of the driving gate $W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i} \ldots$
－the defect random parameter $R_{o p}$
－the pseudo－period $T_{c l}$
－the previous intermediate voltage $V_{j-1}$

In other words，for a given vector $T_{j}$ ，the voltage $V_{j}$ depends on the resistance of the open and on the previous voltage which also depends on the resistance of the open and on the previous voltage which in turn depends on the same parameters．

For a given node，some of the above parameters may be considered as＇constant＇through out the test sequence：$R_{n i}$ ， $C_{n i}, W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i}$ ．Lets call $P$ these constant parameters， we can write：
$V_{j}=V\left(t_{0}+j \cdot T_{c l}+T_{p b j}\right)=F\left(R_{o p}, V_{j-1}, P\right)$
Consequently，at the end of the preparation phase，just before the detection phase（vector $T_{n}$ ），the faulty node $n_{i}$ presents a voltage $V_{n-1}$ which depends on all the previous intermediate voltages through a sort of memory effect．And so it depends on all the previous vectors that have been applied to the circuit．We can write：

$$
\begin{align*}
& -V_{n-1}=V\left(t_{0}+(n-1) \cdot T_{c l}+T_{p b n}-1\right)=F\left(R_{o p}, V_{n-2}, P\right) \\
& -V_{n-2}=V\left(t_{0}+(n-2) \cdot T_{c l}+T_{p b n}-2\right)=F\left(R_{o p}, V_{n-3}, P\right) \\
& -\ldots \\
& -V_{1}=V\left(t_{0}+1 \cdot T_{c l}+T_{p b 1}\right)=F\left(R_{o p}, V_{0}, P\right) \\
\Rightarrow & V_{n-1}=F\left(T_{0}, T_{1}, T_{2}, \ldots, T_{n-1}\right) \tag{11}
\end{align*}
$$

## b）Detection phase

We now analyze the detection phase using again our small example．When vector $T_{6}$ is applied to the circuit，a transition is propagated from input $I_{2}$ to node $n_{4}$ ，the transition is delayed by the resistive open，and finally the delayed transition propagates to output $O_{1}$ ．

This situation is quite similar to the one described for the 2 －vector sequence in the previous section．An input transition is initiated by 2 vectors：the last vector of the preparation phase $T_{5}$ and the vector of the detection phase $T_{6}$ ．So，we come to a similar conclusion：an open with a small resistance can not be detected while an open with a large resistance can be detected．

And so，the resistive open can be detected by the $n$－ vectors sequence $\left\{T_{0}, T_{1}, T_{2}, T_{3}, T_{4}, T_{5}, T_{6}\right\}$ if its unpredictable resistance $R_{o p}$ is larger than a critical resistance called $R_{c}{ }^{\{T 0, T 1, T 2, T 3, T 4, T 5, T 6\}}$ ．Here again，we associate to the resistive open the Detection Interval $D I$ defined below：
$D I^{\{T 0, T 1, T 2, T 3, T 4, T 5, T 6\}}=\left[R_{c}{ }^{\{T 0, T 1, T 2, T 3, T 4, T 5, T 6\}}, \infty\right]$
But there is a fundamental difference between the 2 － vector sequence and the $n$－vector one．In the 2 －vector sequence，the additional delay is a function of the initial voltage $V_{0}=0$ as given by eq．（6）．While，in the $n$－vector sequence，the additional delay $T_{o p}$ is a function of the previous intermediate voltage $V_{n-1}$ ．Indeed，it is clear that the transition in Figure 4 depends on：
－the node electrical parameters $R_{n i}, C_{n i}$
－the strength of the driving gate $W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i} \ldots$
－the defect random parameter $R_{o p}$
－the previous voltage $V_{n-1}$
$\Rightarrow T_{o p}=F\left(R_{o p}, V_{n-1}, R_{n i}, C_{n i}, W^{n}{ }_{i}, L^{n}{ }_{i}, W^{p}{ }_{i}, L^{p}{ }_{i}\right)$

Coming back to our simple example，SPICE simulations show that the critical resistance is equal to $R_{c}{ }^{\{T 0, T 1, T 2, T 3, T 4, T 5, T 6\}}=28 \mathrm{k} \Omega$ ．In other words，any open with a resistance larger than $28 \mathrm{k} \Omega$ can be detected by the 6 －vector sequence．An open with a smaller resistance creates an additional delay which is too small to be detected．

Note that the above range is completely different from the one obtained in the previous section with the 2 －vector sequence $\left\{T_{0}, T_{1}\right\}$ ．This clearly demonstrates the significant impact of the preparation phase on the detection of the resistive open．

## V．ELECTRICAL MODEL OF THE MEMORY EFFECT

In the previous section，simulations of Figure 4 clearly illustrate the series of successive intermediate voltages $V_{1}$ ， $V_{2}, V_{3}, V_{4}, V_{5}$ ．We understood that the logic commutation of the faulty node creates incomplete transitions due to the resistance of the open．

The objective now is to analyze these incomplete transitions using a simplified model of the faulty node．For this purpose，we consider a simple RC model where $C$ is equal to the $C_{n 4}$ capacitance of the circuit of Figure $1\left(C_{n 4}=\right.$ 1.6 fF ），and R has been tuned by simulation such that response of the RC model perfectly fits the simulation of the circuit in Figure 4 where $R_{o p}=7.5 \mathrm{k} \Omega$ ．In fact，the resistance $R$ is＇globally equivalent＇$\left(R_{e q}\right)$ to the transistor resistance of inverter 4 plus the resistance of the open $R_{o p}=7.5 \mathrm{k} \Omega$ ．

Figure 5．Fitting the RC model to the faulty circuit
Figure 5 shows the superimposition of the RC model response and the circuit response．The good agreement between the two responses allows us to use the RC model just with the purpose of analyzing the successive intermediate voltages．

We consider now the situation where an input pulse of amplitude $V_{a}$ is applied to the RC circuit while the voltage of the output is equal to $V_{\text {old }}$ ．The problem being to compute the new voltage $V_{\text {new }}$ as a function of $V_{\text {old }}, R_{\text {eq }}, C_{n 4}$ and the applied pulse $V_{a}$ ．According to the classical equation of a charge of a capacitance through a resistance，the new voltage is given by the following equation：
$V_{\text {new }}=V_{\text {old }}+\Delta V\left(1-e^{-t / R e q C n 4}\right)$
Where $\Delta V$ is the difference between the applied voltage $V_{a}$ and the current voltage $V_{\text {old }}: \Delta V=V_{a}-V_{\text {old }}$

The new voltage is obviously an exponential function of $R_{e q}$ and $C_{n 4}$ ．It is very important to note here that the new voltage is a function of the difference $\Delta V$ between the applied voltage $V_{a}$ and the current voltage $V_{\text {old }}$ ．We also remember that the successive voltages appear with a pseudo－period equal to the period $T_{c l}$ of the circuit． Consequently，the new voltage corresponds to time $t=T_{c l}$ ．

The input vectors create transitions that propagate to the faulty node，but the polarity of the transitions on the faulty node depends on the logic function．The transitions on the faulty node may be positive i．e．from Gnd to $V_{D D}$ ，in this case $\Delta V=V_{D D}-V_{\text {old }}$ or negative i．e．from $V_{D D}$ to Gnd， in this case $\Delta V=0-V_{\text {old }}$ ．We finally obtain the two following equations for the faulty node：

$$
\begin{align*}
& \quad \text { - Positive transition } \\
& V_{\text {new }}=V_{\text {old }}+\left(V_{D D}-V_{\text {old }}\right)\left(1-e^{-T c l / R e q C n 4}\right)  \tag{15}\\
& \quad-\text { Negative transition } \\
& V_{\text {new }}=V_{\text {old }} \cdot e^{-T c l / R e q C n 4} \tag{16}
\end{align*}
$$

Considering the initial state $\left\{T_{0}\right\}$ and the 5 vectors of the preparation phase $\left\{T_{1}, T_{2}, T_{3}, T_{4}, T_{5}\right\}$ of the previous section（Figure 4），we know that node $n_{4}$ should switch from 0 to $1,0,1,1$ ，and 0 ．So，we can use equations 15 and 16 according to these different transitions to compute the successive voltages．Remember that $R_{e q}$ has been set to match the simulation of Figure 4 with $R_{o p}=7.5 \mathrm{k} \Omega$ ．Table 3 summarizes the obtained results．

Table 3：Computed successive intermediate voltages

| Vector | Intermediate <br> Voltages |
| :---: | :--- |
| Initial State | $\mathrm{V} 0=0 \mathrm{~V}$ |
| T 1 | $\mathrm{~V} 1=1.26 \mathrm{~V}$ |
| T 2 | $\mathrm{~V} 2=0.38 \mathrm{~V}$ |
| T3 | $\mathrm{V} 3=1.37 \mathrm{~V}$ |
| T 4 | $\mathrm{~V} 4=1.67 \mathrm{~V}$ |
| T5 | $\mathrm{V} 5=0.50 \mathrm{~V}$ |

The computed successive voltages given in Table 3 perfectly match with the simulated ones in Table 2．This proves that the fundamental cause for the appearance of successive intermediate voltages is due to RC－type phenomenon．Therefore，the RC model can be used to analyze the effect of the preparation phase on the voltage $V_{n-1}$ ．

## VI．CONCLUSION

$\boldsymbol{T}_{\text {his paper analyzes the electrical behavior of a resistive }}$ open as a function of its unpredictable resistance．It is demonstrated that the detection of the resistive open not only depends on the unpredictable resistance but also on the successive intermediate values of the faulty node，i．e． depends on all the vectors that have been applied to the
circuit. An electrical analysis of this memory effect is presented.
