(Received 2 December 2008; accepted 23 September 2009)

We discuss a model consisting of two reservoirs, each with N possible ball locations, at heights E_h and $E_l < E_h$ in a gravitational field. The two reservoirs contain n_h and n_l weight 1 balls. Empty locations are treated as weight 0 balls. The reservoirs are shaken so that all possible ball configurations are equally likely to occur. A cycle consists of exchanging a ball randomly chosen from the higher reservoir and a ball randomly chosen from the lower reservoir. We relate this system to a heat engine and show that the efficiency, which is defined as the ratio of the average work produced to the average energy lost by the higher reservoir, is $1 - E_l/E_h$. When n_l is comparable to n_h , the efficiency is found to coincide with the maximum efficiency $1 - T_l/T_h$, where the temperatures T_l and T_h are defined from a simple expression for the entropy. We also discuss the evaluation of fluctuations and the history of the Carnot discovery. © 2010 American Association of Physics Teachers.

I. INTRODUCTION

The purpose of this paper is to introduce several important thermodynamic concepts in a simple manner. The paper is self-contained and employs only elementary mathematics. The results are derived for a particular urn (or reservoir) model, which is related to the one introduced in 1907 by Ehrenfest.¹⁻³ The model consists of two reservoirs, each with N possible ball locations containing, respectively, n_l and n_h weight 1 balls. These balls are considered indistinguishable. This model is applicable to Otto heat engines (in which the working agent parameter stays fixed when in contact with either bath) with two-level atoms as the working agent.^{4,5}

In Sec. II we describe our model and evaluate the average work produced, the average energy lost by the upper reservoir, and the efficiency. The general properties of heat engines are recalled in Sec. III. The relation between our urn model and the properties of heat engines is discussed in Sec. IV. The absolute temperatures T_h and T_l of the reservoirs are defined in the limit of large ball numbers. When $n_l \approx n_h$, the system efficiency and the average work reduce to the expression for the efficiency and average work given by Carnot for an ideal heat engine. The fluctuations in the work produced are evaluated in Appendix A. A discussion of the history of the Carnot discovery is given in Appendix B.

II. EXCHANGE OF BALLS BETWEEN TWO RESERVOIRS

We consider a system consisting of two reservoirs at heights E_l and $E_h > E_l$ with respect to some lower reference level. There are N possible ball locations in each reservoir, which we label as $1, 2, \dots, N$, as shown in Fig. 1. A single ball is allowed in any given location. The lower reservoir contains n_l weight 1 balls, and the higher reservoir contains n_h weight 1 balls. In Fig. 1 we show an example with $N=5$, $n_h=2$, and $n_l=1$. In the higher reservoir there are ten distin-

guishable ball configurations, and in the lower reservoir there are five distinguishable configurations. The two reservoirs together have $5 \times 10 = 50$ distinguishable configurations, all of which correspond to the same energy. If we assume that the reservoirs are sufficiently shaken between exchange events, all possible ball configurations are equally likely to occur.

We consider ball displacements from the lower and higher reservoirs at a single location, say, the left-most location, labeled 1. We may draw all the possible configurations and evaluate by inspection quantities of interest such as the average work produced by the system. For example, the nine distinguishable configurations for $N=3$, $n_h=2$, and $n_l=1$ are shown in Fig. 2. The number below each configuration is the energy E produced over a cycle, with $E \equiv E_h - E_l = 1$. For example, consider the first position of the first configuration, and note that there is an empty location in the higher reservoir and a ball in the lower reservoir. In this case a cycle consists of transferring the lower-reservoir ball to the higher empty location. The system then delivers an energy equal to -1 , that is, the system absorbs an energy equal to 1. The average energy produced for this configuration, the average work, is $\langle W \rangle = (-1 + 0 + 0 + 0 + 1 + 1 + 0 + 1 + 1) / 9 = 1/3$.

We now turn to an equivalent but more convenient picture involving the uniform probability of choosing a ball from a reservoir. It is then convenient to suppose that empty locations are occupied by weight 0 balls, which do not carry any energy when displaced. A cycle consists of exchanging two balls (of weight 0 or 1), one randomly chosen from the lower reservoir and one randomly chosen from the higher reservoir. The probability of choosing a weight 1 ball from the lower reservoir is $p_l \equiv n_l/N$, and the probability of picking up a weight 1 ball from the higher reservoir is $p_h \equiv n_h/N$. As we will discuss, the average energy produced is $\langle W \rangle = p_h - p_l$. For our example with $N=3$, $n_h=2$, and $n_l=1$, we have $p_l = 1/3$,

Fig. 1. Schematic representation of an engine that converts potential energy into work. Two reservoirs are located at heights E_l and $E_h \geq E_l$, each with N possible ball locations labeled $1, 2, 3, \dots, N$ ($N=5$ in the figure). The number of weight 1 balls (black circles) is n_l in the lower reservoir and n_h in the higher reservoir. Open circles represent weight 0 balls. For each reservoir, every ball configuration is equally likely to occur with the same frequency because the energies are the same. Balls may be transferred from one reservoir to the other in location 1 only. If there is a ball in the upper reservoir at that location and none in the lower one (as is the case in the figure), the ball is transferred from the upper reservoir to the lower one, thereby delivering energy. Conversely, if there is a ball in the lower reservoir and none in the upper one, the ball is transferred from the lower reservoir to the upper one, thereby absorbing energy.

$p_h=2/3$, and $\langle W \rangle = 2/3 - 1/3 = 1/3$, which coincides with the previous result. The equivalence between the two methods is general.

The total energy of the system with n weight 1 balls is $Q = nE$ (with respect to some arbitrary level). The letter Q is employed anticipating a correspondence with thermodynamics. When a weight 1 ball is added to the reservoir at height E , the reservoir energy is incremented by E . If a ball is randomly chosen from the N locations of a reservoir containing n weight 1 balls, the probability that this ball has weight 1 is n/N . Hence, if the chosen ball is subsequently carried to a reservoir at height E , the latter reservoir's average energy is incremented by $\Delta Q = En/N$. The word "average" will henceforth be omitted because only average values will be considered.

Consider two such reservoirs, one at height E_l (lower reservoir) with n_l weight 1 balls and the other at height E_h (higher reservoir) with n_h weight 1 balls. A cycle consists of exchanging two randomly chosen balls between the two reservoirs. The energies added to the lower and higher reservoirs are, respectively,

$$\Delta Q_l = E_l(p_h - p_l), \quad \Delta Q_h = -E_h(p_h - p_l). \quad (1)$$

The work performed follows from conservation of energy

Fig. 2. The nine possible configurations for $N=3$, $n_h=2$, and $n_l=1$. The number below each configuration is the energy produced for one cycle.

$$W = -\Delta Q_l - \Delta Q_h = (E_h - E_l)(p_h - p_l). \quad (2)$$

The engine efficiency, defined as the ratio of the work performed W and the energy $-\Delta Q_h$ lost by the higher reservoir, is therefore

$$\eta \equiv \frac{W}{-\Delta Q_h} = 1 - \frac{E_l}{E_h}. \quad (3)$$

In Sec. IV we show that when $p_h \approx p_l$, the efficiency given in Eq. (3) coincides with the Carnot efficiency, and the work given in Eq. (2) coincides with the expression given by Carnot.

After a cycle the number of weight 1 balls in a reservoir is changed by ± 1 or 0. The next cycle therefore operates with different values of p_l and p_h . We will not consider the evolution of the work produced cycle after cycle. We are interested in a comparison with heat engines operating between two baths whose heat capacity is so large that their temperatures do not vary significantly. Likewise, in the present reservoir model, we may suppose that the number of balls in each reservoir is so large that their change after any number of cycles is insignificant.

III. HEAT ENGINES

In this section we recall some well known facts about heat engines (for a detailed discussion, see, for example, Ref. 6).

It is known empirically that when two bodies at different temperatures are placed in contact, they eventually reach the same temperature. This property may be interpreted by supposing that energy is transferred from the high-temperature body to the low-temperature body but that the converse never occurs. A similar observation can be made with two urns (see Fig. 1 with $E_l = E_h$). Suppose that the urns contain N balls, each of which is either a weight 1 (black) or weight 0 (white) ball. If randomly chosen balls are repeatedly exchanged between the two urns, the ratios of the black and white balls will eventually become nearly the same in both urns independent of the initial conditions. For the analogy with thermal contact to hold, we need to define the temperature of an urn as a monotonically increasing function of the ratio of the number of black to white balls, as long as $n_h < N/2$.

It is also known empirically that when energy is transferred to a body, the body's temperature rises. We say that the body has received energy by heating. The fact that this energy cannot be converted back into usable energy is one form of the second law of thermodynamics. To obtain usable energy from heating, we need two bodies at different temperatures.

Let us now recall how usable energy may be retrieved from two baths at different temperatures. What we need is a "working agent," which may be any piece of material whose properties can be changed by varying a parameter. An example is a helium-filled cylinder with a piston of variable length ϵ . Another example more relevant to this paper is a collection of two-level atoms. We suppose that the separation in energy ϵ of the two levels may be varied by, for example, the application of an electrical field. The external agent that causes the parameter ϵ to vary transfers energy. A typical closed cycle consists of putting the working agent with parameter ϵ_1 in contact with the low-temperature bath and slowly varying ϵ to ϵ_2 . The working agent is then carried from the low-temperature bath to the high-temperature bath,

while ϵ is slowly changed to ϵ_3 . The parameter is then changed to ϵ_4 . The working agent is finally returned to the low-temperature bath, and the parameter recovers its initial ϵ_1 value. A closed cycle is thus defined by the nature of the working agent and four parameter values. When ϵ does not vary the cycle transfers energy from the high-temperature bath to the low-temperature bath and is analogous to a thermal contact.

For the Otto cycle, which describes an idealized form of the gasoline engine,⁷ $\epsilon_2 = \epsilon_1$ and $\epsilon_4 = \epsilon_3$, meaning that the parameter does not vary when the working agent is in contact with either bath; ϵ varies only during the adiabatic (that is, slow and with thermal isolation) transitions from one bath to the other. This cycle may deliver or receive work for appropriate choices of the parameters. Usually it does not achieve the maximum (Carnot) efficiency, but it does so approximately when $\epsilon_4 \approx \epsilon_2$. For the exact description of Carnot heat engines, see the generalization of the ball model in Ref. 8.

IV. ENTROPY AND TEMPERATURE

We consider a reservoir with N locations and n weight 1 balls and $N-n$ weight 0 balls. The number of ball configurations in the reservoir is $N!/n!(N-n)!$.⁹ We define the entropy as the logarithm of the number of configurations, the Boltzmann constant being set equal to unity, that is,

$$S(n) = \ln\left(\frac{N!}{n!(N-n)!}\right). \quad (4)$$

Note that for large n ,

$$S(n+1) - S(n) = \ln\left(\frac{N!}{(n+1)!(N-n-1)!}\right) - \ln\left(\frac{N!}{n!(N-n)!}\right) \quad (5)$$

$$= \ln\left(\frac{N-n}{n+1}\right) \approx \ln\left(\frac{N}{n} - 1\right), \quad (6)$$

The absolute temperature of a reservoir is defined as

$$T(n) = \frac{Q(n+1) - Q(n)}{S(n+1) - S(n)} \approx \frac{E}{\ln\left(\frac{N}{n} - 1\right)}. \quad (7)$$

The entropy S must be an extensive quantity. Because the number of configurations in two separate bodies is the product of the configurations and the logarithmic function has the property that $\ln(ab) = \ln(a) + \ln(b)$, the final approximate expression in Eq. (7) ensures that T is an intensive quantity.

The cycle efficiency given in Eq. (3) may now be written in terms of the temperature as

$$\eta = 1 - \frac{E_l}{E_h} = 1 - \frac{T_l \ln(p_l^{-1} - 1)}{T_h \ln(p_h^{-1} - 1)}. \quad (8)$$

When $p_l \approx p_h$, the last term in Eq. (8) drops out, the Carnot efficiency is obtained, and the work W produced per cycle is very small. However, we may always add up the work contributions of any number of similar devices having the same reservoir temperatures (but possibly different values of E and n) and achieve any specified amount of work at the Carnot efficiency.

The ball exchange we have discussed changes the reservoir entropies by ± 1 or 0. Because these events are independent, the change in the entropy of the lower reservoir is

$$\Delta S_l = p_h(1 - p_l)[S(n_l + 1) - S(n_l)] + p_l(1 - p_h)[S(n_l - 1) - S(n_l)]. \quad (9)$$

From Eq. (6) we obtain

$$\Delta S_l = (p_h - p_l) \ln(p_l^{-1} - 1). \quad (10)$$

The change in the entropy of the higher reservoir is obtained by exchanging the h and l labels in Eq. (10), that is

$$\Delta S_h = -(p_h - p_l) \ln(p_h^{-1} - 1). \quad (11)$$

We thus find that for $p_l \approx p_h$, $\Delta S_l \approx -\Delta S_h$ so that there is no net entropy produced. Entropy is just carried from the higher reservoir to the lower one. The Carnot expression for the work may thus be written as

$$W = (T_h - T_l) \Delta S_l \approx \left(\frac{E_h}{\ln(p_h^{-1} - 1)} - \frac{E_l}{\ln(p_l^{-1} - 1)} \right) \Delta S_l \quad (12)$$

$$\approx (E_h - E_l)(p_h - p_l), \quad (13)$$

so that the Carnot expression for W coincides with the expression for the work performed per cycle evaluated. More precisely, the ratio of the total entropy produced $\Delta S_l + \Delta S_h$ to the work produced W goes to zero as $p_h \rightarrow p_l$ [see Eq. (A4)].

Equation (13) implies that the engine delivers work only if $E_h - E_l$ and $p_h - p_l$ are both positive or both negative. Because $E_h > E_l$, we must have $p_h > p_l$. From Eq. (7) and that the logarithm is a monotonically increasing function of its argument, we find that work may be produced only if $T_h > T_l$.

Conventional heat engines operate with two large baths, or reservoirs, one hot and one cold. Because these baths are not infinite in size, the temperature of the hot bath decreases, and the temperature of the cold bath increases and eventually no work is produced. The same situation occurs in our model. After a very large number of cycles, the values of p_h and p_l coincide, and work is no longer produced. Because the reservoir temperatures do not equalize, we may say that the system has reached a state of equilibrium but not a state of *thermal* equilibrium. This kind of equilibrium is not a peculiarity of our model but a general property of some heat engines.

APPENDIX A: FLUCTUATIONS

We obtain in the following the fluctuations in the work produced and the high-temperature reservoir energy loss. Recall that a cycle consists of simultaneously exchanging a ball from the higher reservoir with n_h weight 1 balls and $N - n_h$ weight 0 balls and a ball from the lower reservoir with n_l weight 1 balls and $N - n_l$ weight 0 balls.

We saw in the main text that the average work produced per cycle is $\langle W \rangle = E(p_h - p_l)$. We now evaluate $\langle W^2 \rangle$. The probability that a weight 1 ball falls and none is raised is $p_h(1 - p_l)$. If this event occurs, the work performed squared is equal to E^2 . Conversely, the probability that a weight 1 ball

is raised and none falls is $p_l(1-p_h)$. If this event occurs, the work performed squared is again equal to E^2 . Because the two other cases produce no work, it follows that $\langle W^2 \rangle = E^2[p_h(1-p_l) + p_l(1-p_h)]$. Therefore, the variance of the work produced is

$$\begin{aligned} \langle W^2 \rangle - \langle W \rangle^2 &= E^2[p_h(1-p_l) + p_l(1-p_h) - (p_h-p_l)^2] \\ &= E^2[p_h(1-p_h) + p_l(1-p_l)]. \end{aligned} \quad (\text{A1})$$

For $p_h \approx p_l$ we have $\langle W^2 \rangle - \langle W \rangle^2 \approx 2E^2 p_l(1-p_l)$.

We now consider the total entropy produced $\Delta S \equiv \Delta S_l + \Delta S_h$. When a weight 1 ball is transferred from the high to the lower reservoir and none from the low to the higher reservoir, an event that occurs with probability $p_h(1-p_l)$, the change in S_l according to Eq. (6) is $\Delta S(n_l+1) - \Delta S(n_l) = \ln(p_l^{-1}-1)$, and the change in S_h is $\Delta S(n_h-1) - \Delta S(n_h) = -\ln(p_h^{-1}-1)$. It follows that the change in the total entropy is $\ln((p_l^{-1}-1)/(p_h^{-1}-1))$ with probability $p_h(1-p_l)$. When a ball is transferred from the low to the higher reservoir and none from the high to the lower reservoir, an event that occurs with probability $p_l(1-p_h)$, the change in S_l is, according to Eq. (6), $\Delta S(n_l-1) - \Delta S(n_l) = -\ln(p_l^{-1}-1)$, and the change in S_h is $\Delta S(n_h+1) - \Delta S(n_h) = \ln(p_h^{-1}-1)$. It follows that the change in the total entropy is $\ln((p_h^{-1}-1)/(p_l^{-1}-1))$ with probability $p_l(1-p_h)$.

The average change in the total entropy is therefore

$$\langle \Delta S \rangle = p_h(1-p_l) \ln\left(\frac{p_l^{-1}-1}{p_h^{-1}-1}\right) + p_l(1-p_h) \ln\left(\frac{p_h^{-1}-1}{p_l^{-1}-1}\right) \quad (\text{A2})$$

$$= (p_h - p_l) \ln\left(\frac{p_l^{-1}-1}{p_h^{-1}-1}\right) \geq 0. \quad (\text{A3})$$

When $p_h \approx p_l$, $\Delta S \approx 0$, and the system becomes reversible and achieves the highest efficiency. Note that the entropy change is non-negative for both a heat engine ($p_h > p_l$) and a heat pump ($p_l > p_h$). More precisely, to first order in $\delta \equiv p_h - p_l$ we have $\ln[(p_l^{-1}-1)/(1/p_h^{-1}-1)] \approx \delta/[p_l(1-p_l)]$, and thus

$$\langle \Delta S \rangle \approx \frac{\delta^2}{p_l(1-p_l)}. \quad (\text{A4})$$

This result is reasonable because the entropy is proportional to δ^2 , and the work produced is proportional to δ so that for small δ , near reversibility does not imply vanishing work.

We also obtain

$$\begin{aligned} \langle (\Delta S)^2 \rangle &= p_h(1-p_l) \left[\ln\left(\frac{p_l^{-1}-1}{p_h^{-1}-1}\right) \right]^2 \\ &\quad + p_l(1-p_h) \left[\ln\left(\frac{p_h^{-1}-1}{p_l^{-1}-1}\right) \right]^2 \end{aligned} \quad (\text{A5})$$

$$= (p_h + p_l - 2p_l p_h) \left[\ln\left(\frac{p_l^{-1}-1}{p_h^{-1}-1}\right) \right]^2, \quad (\text{A6})$$

and the variance is

$$\begin{aligned} \langle (\Delta S)^2 \rangle - \langle \Delta S \rangle^2 &= (p_h + p_l - 2p_l p_h \\ &\quad - (p_h - p_l)^2) \left[\ln\left(\frac{p_l^{-1}-1}{p_h^{-1}-1}\right) \right]^2 \end{aligned} \quad (\text{A7})$$

$$\begin{aligned} &= [p_h(1-p_h) + p_l(1-p_l)] \\ &\quad \times \left[\ln\left(\frac{p_l^{-1}-1}{p_h^{-1}-1}\right) \right]^2, \end{aligned} \quad (\text{A8})$$

which vanishes, as well as the average entropy produced, when $p_h \approx p_l$. To first order in δ we have

$$\langle (\Delta S)^2 \rangle - \langle \Delta S \rangle^2 \approx 2\langle \Delta S \rangle, \quad (\text{A9})$$

a remarkably simple result. This result was given in Ref. 10 and in previous work.^{11,12} This agreement shows that the properties of our model are generally applicable to heat engines.

APPENDIX B: BRIEF HISTORY OF CARNOT'S DISCOVERIES

The motivation for introducing the following account of Carnot discoveries is that they remain insufficiently appreciated.

The Carnot theory, which appeared in a book in 1824 and in unpublished notes, established both the first and the second laws of thermodynamics.¹³ This fact has been pointed out by several authors who have looked carefully at what Carnot actually wrote, clarifying the terminology employed, updating the system of units, and correcting minor errors in the experimental data. We translate from Kastler's paper:¹⁴ "Had Sadi Carnot lived longer [...], he would be considered today not only as the author of the Carnot principle (called by Clausius the second principle of thermodynamics) but also as the author of the first principle of that science." The book by Brodiansky¹³ lists ten major achievements of Carnot, including that "Carnot is the first to formulate the second principle of thermodynamics" and "He was among the first to formulate strictly the law of equivalence between heat and work and the first to calculate with sufficient accuracy its numerical value."

One reason for the lack of appreciation of Carnot's contribution is that it appeared in print decades after his early death. A second reason is that his work was popularized by Clapeyron in a partly erroneous manner. A third reason is the unfortunate use by Carnot of the word "calorique" to designate what Clausius later called "entropy." The word calorique had been formerly employed by Lavoisier to designate some hypothetical heat substance. Clausius and Lord Kelvin, although highly appreciative of Carnot's work, missed part of his contribution because Carnot's notes were not available to them. La Mer expressed himself forcefully as follows: "Unless the view-point that the Carnot theory is accurate is adopted, one is placed in the position of maintaining that Carnot succeeded in demonstrating some of the most fundamental and profound principles of physical science by the most masterly display of scientific double-talk that has ever been perpetrated upon the scientific world. This view is untenable."¹⁵ Much clarification is due to Hoyer.¹⁶ The historian of science Fox has written, "Until recently there were very few studies concerning [the physics of Carnot reflections]. Thanks to the work of Hoyer, we now have papers on the logical implications of the Carnot theory, and its analogy

with modern thermodynamics [...]. It is not at all obvious to understand how Carnot [discovered the mechanical equivalent of heat]. Hoyer examined this question in two important papers. His articles provide complete references to earlier attempts [...]. He explains the exactness of Carnot calculation (which is even more striking if one uses modern values for the specific heats) by noticing that the Carnot theory is entirely accurate.”

As far as the first law of thermodynamics is concerned, we quote Carnot:¹⁷ “Heat is nothing but motive power, or rather another form of motion. Wherever motive power is destroyed, heat is generated in precise proportion to the quantity of motive power destroyed; conversely, wherever heat is destroyed, motive power is generated.” (Carnot calculated that 1 cal is equivalent to 3.27 J instead of the present-day value of 4.18 J.)

The key fact related to the second law is that engine efficiencies reach their maximum value when they are reversible. Carnot reached this conclusion by considering that energy cannot be obtained for free. He therefore looked for energy transfers that could work in a reversed manner. Slow processes are reversible, with the exception of thermal contacts. Because there is some confusion in the literature concerning the significance of the Carnot contribution to the second law of thermodynamics, we quote Zemansky and Dittman:⁶ “Carnot used *chaleur* when referring to heat in general, but when referring to the motive power of fire that is brought about when heat enters an engine at high temperature and leaves at low temperature, he uses the expression *chute de calorique*, never *chute de chaleur* [...]. Carnot had in the back of his mind the concept of entropy, for which he reserved the term *calorique*.”
