Abstract

Asynchronous Backtracking is the standard search procedure for distributed constraint reasoning. It requires a total ordering on the agents. All polynomial space algorithms proposed so far to improve Asynchronous Backtracking by reordering agents during search only allow a limited amount of reordering. In this paper, we propose Agile-ABT, a search procedure that is able to change the ordering of agents more than previous approaches. This is done via the original notion of termination value, a vector of stamps labelling the new orders exchanged by agents during search. In Agile-ABT, agents can reorder themselves as much as they want as long as the termination value decreases as the search progresses. Our experiments show the good performance of Agile-ABT when compared to other dynamic reordering techniques.

1 Introduction

Various application problems in distributed artificial intelligence are concerned with finding a consistent combination of agent actions (e.g., distributed resource allocation [6], sensor networks [1]). Such problems can be formalized as Distributed Constraint Satisfaction Problems (DisCSPs). DisCSPs are composed of agents, each owning its local constraint network. Variables in different agents are connected by constraints. Agents must assign values to their variables so that all constraints between agents are satisfied. Several distributed algorithms for solving DisCSPs have been developed, among which Asynchronous Backtracking (ABT) is the central one [10, 2]. ABT is an asynchronous algorithm executed autonomously by each agent in the distributed problem. Agents do not have to wait for decisions of others but they are subject to a total (priority) order. Each agent tries to find an assignment satisfying the constraints with what is currently known from higher priority agents. When an agent assigns a value to its variable, the selected value is sent to lower priority agents. When no value is possible for a variable, the inconsistency is reported to higher agents in the form of a nogood. ABT computes a solution (or detects that no solution exists) in a finite time. The total order is static. Now, it is known from centralized CSPs that adapting the order of variables dynamically during search drastically fastens the search procedure.

Asynchronous Weak Commitment (AWC) dynamically reorders agents during search by moving the sender of a nogood higher in the order than the other agents in the nogood [9]. But AWC requires exponential space for storing nogoods. Silaghi et al. (2001) tried to hybridize ABT with AWC. Abstract agents fulfill the reordering operation to guarantee a finite number of asynchronous reordering operations. In [7], the heuristic of the centralized dynamic backtracking was applied to ABT. However, in both studies, the improvement obtained on ABT was minor.

Zivan and Meisels (2006) proposed Dynamic Ordering for Asynchronous Backtracking (ABTDO). When an agent assigns value to its variable, ABTDO can reorder lower priority agents. A new kind of ordering heuristics for ABTDO is presented in [13]. In the best of those heuristics, the agent that generates a nogood is placed between the last and the second last agents in the nogood if its domain size is smaller than that of the agents it passes on the way up.
In this paper, we propose Agile-ABT, an asynchronous dynamic ordering algorithm that does not follow the standard restrictions in asynchronous backtracking algorithms. The order of agents appearing before the agent receiving a backtrack message can be changed with a great freedom while ensuring polynomial space complexity. Furthermore, that agent receiving the backtrack message, called the backtracking target, is not necessarily the agent with the lowest priority within the conflicting agents in the current order. The principle of Agile-ABT is built on termination values exchanged by agents during search. A termination value is a tuple of positive integers attached to an order. Each positive integer in the tuple represents the expected current domain size of the agent in that position in the order. Orders are changed by agents without any global control so that the termination value decreases lexicographically as the search progresses. Since, a domain size can never be negative, termination values cannot decrease indefinitely. An agent informs the others of a new order by sending them its new order and its new termination value. When an agent compares two contradictory orders, it keeps the order associated with the smallest termination value.

The rest of the paper is organized as follows. Section 2 recalls basic definitions. Section 3 describes the concepts needed to select new orders that decrease the termination value. We give the details of our algorithm in Section 4 and we prove it in Section 5. An extensive experimental evaluation is given in Section 6. Section 7 concludes the paper.

2 Preliminaries

The Distributed Constraint Satisfaction Problem (DisCSP) has been formalized in [10] as a tuple \((A, X, D, C)\), where \(A\) is a set of agents, \(X\) is a set of variables \(\{x_1, \ldots, x_n\}\), where each variable \(x_i\) is controlled by one agent in \(A\). \(D = \{D_1, \ldots, D_n\}\) is a set of domains, where \(D_i\) is a finite set of values to which variable \(x_i\) may be assigned. The initial domain size of a variable \(x_i\) is denoted by \(d_i^0\). \(C\) is a set of binary constraints that specify the combinations of values allowed for the two variables they involve. A constraint \(c_{ik} \in C\) between two variables \(x_i\) and \(x_k\) is a subset of the Cartesian product \(D_i \times D_k\).

For simplicity purposes, we consider a restricted version of DisCSP where each agent controls exactly one variable. We use the terms agent and variable interchangeably and we identify the agent ID with its variable index. All agents maintain their own counter, and increment it whenever they change their value. The current value of the counter tags each generated assignment.

**Definition 1** An assignment for an agent \(A_i \in A\) is a tuple \((x_i, v_i, t_i)\), where \(v_i\) is a value from the domain of \(x_i\) and \(t_i\) is the tag value. When comparing two assignments, the most up to date is the one with the highest tag \(t_i\). Two sets of assignments \(\{(x_{i1}, v_{i1}, t_{i1}), \ldots, (x_{ih}, v_{ih}, t_{ih})\}\) and \(\{(x_{j1}, v_{j1}, t_{j1}), \ldots, (x_{jq}, v_{jq}, t_{jq})\}\) are coherent if every common variable is assigned the same value in both sets.

\(A_i\) is allowed to store a unique order denoted by \(o_i\). Agents appearing before \(A_i\) in \(o_i\) are the higher agents (predecessors) denoted by \(\text{Pred}(A_i)\) and conversely the lower agents (successors) \(\text{Succ}(A_i)\) are agents appearing after \(A_i\).
**Definition 2** The AgentView of an agent $A_i$ is an array containing the most up to date assignments of $\text{Pred}(A_i)$.

Agents can infer inconsistent sets of assignments, called nogoods. A nogood can be represented as an implication. There are clearly many different ways of representing a given nogood as an implication. For example, $\neg((x_1=v_1) \land \cdots \land (x_k=v_k))$ is logically equivalent to $[(x_2=v_2) \land \cdots \land (x_k=v_k) \rightarrow (x_1 \neq v_1)]$. When a nogood is represented as an implication, the left hand side ($\text{lhs}$) and the right hand side ($\text{rhs}$) are defined from the position of $\rightarrow$. A nogood $ng$ is compatible with an order $o_i$ if all agents in $\text{lhs}(ng)$ appear before $\text{rhs}(ng)$ in $o_i$.

The current domain of $x_i$ is the set of values $v \in D_i$ such that $x_i \neq v$ does not appear in any of the right hand sides of the nogoods stored by $A_i$. Each agent keeps only one nogood per removed value. The size of the current domain of $A_i$ is denoted by $d_i$.

## 3 Introductory Material

Before presenting Agile-ABT, we need to introduce new notions and to present some key subfunctions.

### 3.1 Reordering details

There is one major issue to be solved for allowing agents to asynchronously propose new orders: The agents must be able to coherently decide which order to select. We propose that the priority between the different orders is based on termination values. Informally, if $o_i = [A_1, \ldots, A_n]$ is the current order known by an agent $A_i$, then the tuple of domain sizes $[d_1, \ldots, d_n]$ is the termination value of $o_i$ on $A_i$. To build termination values, agents need to exchange explanations.

**Definition 3** An explanation $e_j$ is an expression of the form $\text{lhs}(e_j) \rightarrow d_j$, where $\text{lhs}(e_j)$ is the conjunction of the left hand sides of all nogoods stored by $A_j$ as justifications of value removals, and $d_j$ is the number of values not pruned by nogoods in the domain of $A_j$. $d_j$ is also denoted by $\text{rhs}(e_j)$.

Each time an agent communicates its assignment to other agents (by sending them an ok? message), it inserts its explanation in the ok? message for allowing other agents to build their termination value.

The variables in the left hand side of an explanation $e_j$ must precede the variable $x_j$ in the order because the assignments of these variables have been used to determine the current domain of $x_j$. An explanation $e_j$ induces ordering constraints, called safety conditions in [4].

**Definition 4** A safety condition is an assertion $x_k \prec x_j$. Given an explanation $e_j$, $S(e_j)$ is the set of safety conditions induced by $e_j$, where $S(e_j) = \{(x_k \prec x_j) \mid x_k \in \text{lhs}(e_j)\}$.
An explanation $e_j$ is **compatible** with an order $o$ if all variables in $lhs(e_j)$ appear before $x_j$ in $o$. Each agent $A_i$ stores a set $E_i$ of explanations sent by other agents. During search, $E_i$ is updated to remove explanations that are no longer valid.

**Definition 5** An explanation $e_j$ in $E_i$ is valid on agent $A_i$ if it is compatible with the current order $o_i$ and $lhs(e_j)$ is coherent with the AgentView of $A_i$.

When $E_i$ contains an explanation $e_j$ associated with $A_j$, $A_i$ uses this explanation to justify the size of the current domain of $A_j$. Otherwise, $A_i$ assumes that the size of the current domain of $A_j$ is equal to $d^0_j$. The termination value depends on the order and the set of explanations.

**Definition 6** Let $E_i$ be the set of explanations stored by $A_i$, $o$ be an order on the agents such that every explanation in $E_i$ is compatible with $o$, and $o(k)$ be such that $A_{o(k)}$ is the $k$th agent in $o$. The termination value $TV(E_i, o)$ is the tuple $[tv^1, \ldots, tv^n]$, where $tv^k = rhs(e_{o(k)})$ if $e_{o(k)} \in E_i$, otherwise, $tv^k = d^0_{o(k)}$.

In Agile-ABT, an order is always associated with a termination value. When comparing two orders the *strongest* order is that associated with the lexicographically smallest termination value. In case of ties, we use the lexicographic order on agents IDs, the smallest being the strongest. Consider for instance the two orders $o_1 = [A_1, A_2, A_5, A_4, A_3]$ and $o_2 = [A_1, A_2, A_4, A_5, A_3]$ where agents are ordered according to their IDs from left to right. If the termination value associated with $o_1$ is equal to the termination value associated with $o_2$, $o_2$ is stronger than $o_1$ because the vector $[1, 2, 4, 5, 3]$ of IDs in $o_2$ is lexicographically smaller than the vector $[1, 2, 5, 4, 3]$ of IDs in $o_1$.

### 3.2 The backtracking target

When all values of an agent $A_i$ are ruled out by nogoods, these nogoods are resolved, producing a new nogood $ng$. $ng$ is the conjunction of $lhs$ of all nogoods stored by $A_i$. If $ng$ is empty, then the inconsistency is proved. Otherwise, one of the conflicting agents must change its value. In standard ABT, the agent that has the lowest priority must change its value. Agile-ABT overcomes this restriction by allowing $A_i$ to select with great freedom the target agent $A_k$ who must change its value (i.e., the variable to place in the right hand side of $ng$). The only restriction to place a variable $x_k$ in the right hand side of $ng$ is to find an order $o'$ such that $TV(up_{\varphi}E, o')$ is lexicographically smaller than the termination value associated with the current order of $A_i$. $up_{\varphi}E$ is obtained by updating $E_i$ after placing $x_k$ in $rhs(ng)$.

Function updateExplanations takes as arguments the set $E_i$, the nogood $ng$ and the variable $x_k$ to place in the $rhs$ of $ng$. updateExplanations removes all explanations that are no longer coherent after placing $x_k$ in the right hand side of $ng$. It updates the explanation of agent $A_k$ stored in $A_i$ and it returns a set of explanations $up_{\varphi}E$.

This function does not create cycles in the set of safety conditions $S(up_{\varphi}E)$ if $S(E_i)$ is acyclic. Indeed, all the explanations added or removed from $S(E_i)$ to obtain $S(up_{\varphi}E)$ contain $x_k$. Hence, if $S(up_{\varphi}E)$ contains cycles, all these cycles should
function updateExplanations(Ei, ng, xk)
1. up_E ← Ei;
2. setRhs (ng, xk);
3. remove each e_j ∈ up_E such that x_k ∈ lhs (e_j);
4. if (e_k ∉ up_E) then
5. setLhs (e_k, ∅);
6. setRhs (e_k, d_k);
7. add e_k to up_E;
8. setLhs (e'_k, lhs (e_k) ∪ lhs (ng));
9. setRhs (e'_k, rhs (e_k) − 1);
10. replace e_k by e'_k;
11. return up_E;

contain x_k. However, there does not exist any safety condition of the form x_k ≺ x_j in S(up_E) because all of these explanations have been removed in line 3. Thus, S(up_E) cannot be cyclic. As we will show in Section 4, the updates performed by A_i ensure that S(E_i) always remains acyclic. As a result, S(up_E) is acyclic as well, and it can be represented by a directed acyclic graph G = (N, U) such that N = {x_1, . . . , x_n} is the set of nodes and U is the set of directed edges. An edge (j, l) ∈ U if (x_j ≺ x_l) ∈ S(up_E). Thus, any topological sort of G is an order that agrees with the safety conditions induced by up_E.

3.3 Decreasing termination values
Termination of Agile-ABT is based on the fact that the termination values associated with orders selected by agents decrease as search progresses. To speed up the search, Agile-ABT is written so that agents decrease termination values whenever they can. When an agent resolves its nogoods, it checks whether it can find a new order of agents such that the associated termination value is smaller than that of the current order. If so, the agent will replace its current order and termination value by those just computed, and will inform all other agents.

Assume that after resolving its nogoods, an agent A_i, decides to place x_k in the rhs of the nogood (ng) produced by the resolution and let up_E = updateExplanations (E_i, ng, x_k). The function computeOrder takes as parameter the set up_E and returns an order up_φ compatible with the partial ordering induced by up_E. Let G be the acyclic directed graph associated with up_E. The function computeOrder works by determining, at each iteration p, the set Roots of vertices that have no predecessor. As we aim at minimizing the termination value, function computeOrder selects the vertex x_j in Roots that has the smallest domain size. This vertex is placed at the pth position and removed from G. Finally, p is incremented and all outgoing edges from x_j are removed from G.

Having proposed an algorithm that determines an order with small termination value for a given backtracking target x_k, one needs to know how to choose this variable to obtain an order decreasing more the termination value. The function chooseVariableOrder iterates through all variables x_k included in the nogood, computes a new order and termination value with x_k as the target (lines 22–24), and stores
function computeOrder(up\_E)
12. \[ G = (N, U) \] is the acyclic graph associated to up\_E;
13. \[ p \leftarrow 1; \] \( o \) is an array of length \( n \);
14. while \( G \neq \emptyset \) do
15. \[ \text{Roots} \leftarrow \{ x_j \in N \mid x_j \text{ has no incoming edges} \}; \]
16. \[ o[p] \leftarrow x_j \text{ such that } d_j = \min\{d_k \mid x_k \in \text{Roots} \}; \]
17. remove \( x_j \) from \( G \);
18. \[ p \leftarrow p + 1; \]
19. return \( o \);

the target and the associated order if it is the strongest order found so far (lines 25–29). Finally, the information corresponding to the strongest order is returned.

function chooseVariableOrder(E\_i, ng)
20. \[ o' \leftarrow o_i; \] TV' \leftarrow TV_i; E' \leftarrow \text{nil}; x' \leftarrow \text{nil};
21. for each \( x_k \in ng \) do
22. \[ \text{updateExplanations}(E_i, ng, x_k); \]
23. \[ \text{computeOrder}(\text{up}_E); \]
24. \[ \text{TV}' \leftarrow \text{TV}(\text{up}_E, \text{up}_o); \]
25. \[ \text{if } (\text{up}_E \text{ is smaller than } TV') \text{ then} \]
26. \[ x' \leftarrow x_k; \]
27. \[ o' \leftarrow \text{up}_E; \]
28. \[ TV' \leftarrow \text{up}_E \text{TV}; \]
29. \[ E' \leftarrow \text{up}_E; \]
30. return \( \langle x', o', TV', E' \rangle \);

4 The Algorithm

Each agent keeps some amount of local information about the global search, namely an AgentView, a NogoodStore, a set of explanations \( (E_i) \), a current order \( (o_i) \) and a termination value \( (TV_i) \). Agile-ABT allows the following types of messages (where \( A_i \) is the sender):

- **ok?** message is sent by \( A_i \) to lower agents to ask whether a chosen value is acceptable. Besides the chosen value, the ok? message contains an explanation \( e_i \) which communicates the current domain size of \( A_i \). An ok? message also contains the current order \( o_i \) and the current termination value \( TV_i \) stored by \( A_i \).

- **ngd** message is sent by \( A_i \) when all its values are ruled out by its NogoodStore. This message contains a nogood, as well as \( o_i \) and \( TV_i \).

- **order** message is sent to propose a new order. This message includes the order \( o_i \) proposed by \( A_i \), accompanied by the termination value \( TV_i \).

Agile-ABT (Figures 1 and 2) is executed on every agent \( A_i \). After initialization, each agent assigns a value and informs lower priority agents of its decision (CheckAgentView call, line 32) by sending ok? messages. Then, a loop considers the reception of the possible message types. If no message is traveling through the

end function 

Figure 2: The Agile-ABT algorithm (Part 2).

network, the state of quiescence is detected by a specialized algorithm [5], and a global solution is announced. The solution is given by the current variables’ assignments. When an agent \( A_i \) receives a message (of any type), it checks if the order included in the received message is stronger than its current order \( o_i \) (CheckOrder call, lines 40, 44 and 46). If it is the case, \( A_i \) replaces \( o_i \) and \( TV_i \) by those newly received (line 53). The nogoods and explanations that are no longer compatible with \( o_i \) are removed to ensure that \( S(E_i) \) remains acyclic (line 54).

If the message was an \textit{ok?} message, the AgentView of \( A_i \) is updated to include the new assignments (UpdateAgentView call, line 41). Beside the assignment of the sender, \( A_i \) also takes newer assignments contained in the left hand side of the explanation included in the received \textit{ok?} message to update its AgentView. Afterwards, the nogoods and the explanations that are no longer coherent with AgentView are removed (UpdateAgentView line 64). Then, if the explanation in the received message is valid, \( A_i \) updates the set of explanations by storing the newly received explanation. Next, \( A_i \) calls the procedure CheckAgentView (line 43).

When receiving an \textit{order} message, \( A_i \) processes the new order (CheckOrder) and calls CheckAgentView (line 45).

When \( A_i \) receives a \textit{nzd} message, it calls CheckOrder and UpdateAgentView (lines 46 and 47). The nogood contained in the message is accepted if it is coherent with the AgentView and the assignment of \( x_i \) and compatible with the current order of \( A_i \). Otherwise, the nogood is discarded and an \textit{ok?} message is sent to the sender.
as in ABT (lines 51 and 52). When the nogood is accepted, it is stored, acting as justification for removing the current value of $A_i$ (line 49). A new value consistent with the AgentView is searched (CheckAgentView call, line 50).

The procedure CheckAgentView checks if the current value $v_i$ is consistent with the AgentView. If $v_i$ is consistent, $A_i$ checks if $o_i$ was modified (line 59). If so, $A_i$ must send its assignment to lower priority agents through ok? messages. If $v_i$ is not consistent with its AgentView, $A_i$ tries to find a consistent value (ChooseValue call, line 56). In this process, some values of $A_i$ may appear as inconsistent. In this case, the nogoods justifying their removal are added to the NogoodStore (line 81 of function ChooseValue). If a new consistent value is found, an explanation $e_i$ is built and the new assignment is notified to the lower priority agents of $A_i$ through ok? messages (line 57). Otherwise, every value of $A_i$ is forbidden by the NogoodStore and $A_i$ has to backtrack (Backtrack call, line 58).

In procedure Backtrack, $A_i$ resolves its nogoods, deriving a new nogood (ng). If ng is empty, the problem has no solution. $A_i$ terminates execution after sending a stp message (line 66). Otherwise, one of the agents included in ng must change its value. The function chooseVariableOrder selects the variable to be changed ($x_k$) and a new order ($o'$) such that the new termination value $TV'$ is as small as possible. If $TV'$ is smaller than that stored by $A_i$, the current order and the current termination value are replaced by $o'$ and $TV'$ and $A_i$ updates its explanations by that returned by chooseVariableOrder (line 69). Then, a ngd message is sent to the agent $A_k$ owner of $x_k$ (line 71). Then, $e_k$ is removed from $E_i$ since $A_k$ will probably change its explanation after receiving the nogood (line 72). Afterwards, $A_i$ sends an order message to all other agents (line 73). When $TV'$ is not smaller than the current termination value, $A_i$ cannot propose a new order and the variable to be changed ($x_k$) is the variable that has the lowest priority according to the current order of $A_i$ (lines 75 and 76). Next, the assignment of $x_k$ (the target of the backtrack) is removed from the AgentView of $A_i$ (line 77). Finally, the search is continued by calling the procedure CheckAgentView (line 78).

5 Correctness and complexity

In this section we demonstrate that Agile-ABT is sound, complete and terminates, and that its space complexity is polynomially bounded.

**Theorem 1** The spatial complexity of Agile-ABT is polynomial.

**Proof.** The size of nogoods, explanations, termination values, and orderings, is bounded by $n$, the total number of variables. Now, on each agent, Agile-ABT only stores one nogood per value, one explanation per agent, one termination value and one ordering. Thus, the space complexity of Agile-ABT is in $O(nd + n^2 + n + n) = O(nd + n^2)$ on each agent. □
Theorem 2 The algorithm Agile-ABT is sound.

Proof. Let us assume that the state of quiescence is reached. The order (say \(o\)) known by all agents is the same because when an agent proposes a new order, it sends it to all other agents. Obviously, \(o\) is the strongest order that has ever been calculated by agents. Also, the state of quiescence implies that every pair of constrained agents satisfies the constraint between them. To prove this, assume that there exist some constraints that are not satisfied. This implies that there are at least two agents \(A_i\) and \(A_k\) that do not satisfy the constraint between them. Let \(A_i\) be the agent which has the highest priority between the two agents according to \(o\). Let \(v_i\) be the current value of \(A_i\) when the state of quiescence is reached (i.e., \(v_i\) is the most up-to-date assignment of \(A_i\)) and let \(M\) be the last \textit{ok?} message sent by \(A_i\) before the state of quiescence is reached. Clearly, \(M\) contains \(v_i\), otherwise, \(A_i\) would have sent another \textit{ok?} message when it chose \(v_i\). Moreover, when \(M\) was sent, \(A_i\) already knew the order \(o\), otherwise \(A_i\) would have sent another \textit{ok?} message to its successors according to \(o\) (including \(A_k\)). The only case where \(A_k\) can forget \(v_i\) after receiving it is the case where \(A_k\) derives a nogood proving that \(v_i\) is not feasible. In this case, \(A_k\) should send a nogood message to \(A_i\). If the nogood message is accepted by \(A_i\), \(A_i\) must send an \textit{ok?} message to its successors (and therefore \(M\) is not the last one). Similarly, if the nogood message is discarded, \(A_i\) have to re-send an \textit{ok?} message to \(A_k\) (and therefore \(M\) is not the last one). So the state of quiescence implies that \(A_k\) knows both \(o\) and \(v_i\). Thus, the state of quiescence implies that the current value of \(A_k\) is consistent with \(v_i\), otherwise \(A_k\) would send at least a message and our quiescence assumption would be broken.

\[\square\]

Theorem 3 The algorithm Agile-ABT is complete.

Proof. All nogoods are generated by logical inferences from existing constraints. Therefore, an empty nogood cannot be inferred if a solution exists.

In order to prove that Agile-ABT terminates, we first establish two facts by proving lemmas 1 and 2.

Lemma 1 For any agent \(A_i\), while a solution is not found and the inconsistency of the problem is not proved, the termination value stored by \(A_i\) decreases after a finite amount of time.

Proof. Let \(TV_i = [tv^1, \ldots, tv^n]\) be the current termination value of \(A_i\). Assume that \(A_i\) reaches a state where it cannot improve its termination value. If another agent succeeds in generating a termination value smaller than \(TV_i\), lemma 1 holds since \(A_i\) will receive the new termination value. Now assume that Agile-ABT reaches a state \(\sigma\) where no agent can generate a termination value smaller than \(TV_i\). We show that Agile-ABT will exit \(\sigma\) after a finite amount of time. Let \(t\) be the time when Agile-ABT reaches the state \(\sigma\). After a finite time \(\delta t\), the termination value of each agent \(A_j\in\{1,\ldots,n\}\) will be equal to \(TV_i\), either because \(A_j\) has generated itself a termination value equal to \(TV_i\) or because \(A_j\) has received \(TV_i\) in an order message. Let \(o\) be the lexicographically smallest order among the current orders of all agents at time \(t+\delta t\).
The termination value associated with \( o \) is equal to \( TV_i \). While Agile-ABT is getting stuck in \( \sigma \), no agent will be able to propose an order stronger than \( o \) because no agent is allowed to generate a new order with the same termination value as the one stored (Figure 2, line 68). Thus, after a finite time \( \delta' t \), all agents will receive \( o \). They will take it as their current order and Agile-ABT will behave as ABT, which is known to be complete and to terminate.

We know that \( d_{o(i)}^0 - tv^1 \) values have been removed once and for all from the domain of the variable \( x_{o(i)} \) (i.e., \( d_{o(i)}^0 - tv^1 \) nogoods with empty \( lhs \) have been sent to \( A_{o(i)} \)). Otherwise, the generator of \( o \) could not have put \( A_{o(i)} \) in the first position. Thus, the domain size of \( x_{o(i)} \) cannot be greater than \( tv^1 \) \((d_{o(i)}^0 \leq tv^1)\). After a finite amount of time, if a solution is not found and the inconsistency of the problem is not proved, a nogood –with an empty \( lhs \)– will be sent to \( A_{o(i)} \) which will cause it to replace its assignment and to reduce its current domain size \((d_{o(i)}' = d_{o(i)} - 1)\). The new assignment and the new current domain size of \( A_{o(i)} \) will be sent to the \((n - 1)\) lower priority agents. After receiving this message, we are sure that any generator of a new nogood (say \( A_{k} \)) will improve the termination value. Indeed, when \( A_{k} \) resolves its nogoods, it computes a new order such that its termination value is minimal. At worst, \( A_{k} \) can propose a new order where \( A_{o(i)} \) keeps its position. Even in this case the new termination value \( TV_k' = [d_{o(i)}', \ldots] \) is lexicographically smaller than \( TV_i = [tv^1, \ldots] \) because \( d_{o(i)}' = d_{o(i)} - 1 \leq tv^1 - 1 \). After a finite amount of time, all agents \((A_i \text{ included})\) will receive \( TV_k' \). This will cause \( A_{i} \) to update its termination value and to exit the state \( \sigma \). This completes the proof.

**Lemma 2** Let \( TV = [tv^1, \ldots, tv^n] \) be the termination value associated with the current order of any agent. We have \( tv^j \geq 0, \forall j \in 1..n \)

**Proof.** Let \( A_i \) be the agent that generated \( TV \). We first prove that \( A_i \) never stores an explanation with a \( rhs \) smaller than 1. An explanation \( e_k \) stored by \( A_i \) was either sent by \( A_k \) or generated when calling \( \text{chooseVariableOrder} \). If \( e_k \) was sent by \( A_k \), we have \( rhs(e_k) \geq 1 \) because the size of the current domain of any agent is always greater than or equal to 1. If \( e_k \) was computed by \( \text{chooseVariableOrder} \), the only case where \( rhs(e_k) \) is made smaller than the right hand side of the previous explanation stored for \( A_k \) by \( A_i \) is in line 9 of \( \text{updateExplanations} \). This happens when \( s_x \) is selected to be the backtracking target (lines 22 and 29 of \( \text{chooseVariableOrder} \)) and in such a case, the explanation \( e_k \) is removed just after sending the nogood message to \( A_k \) (Figure 2, line 72 of Backtrack). Hence, \( A_i \) never stores an explanation with a \( rhs \) equal to zero.

We now prove that it is impossible that \( A_i \) generated \( TV \) with \( tv^j < 0 \) for some \( j \). From the point of view of \( A_i \), \( tv^j \) is the size of the current domain of \( A_{o(j)} \). If \( A_i \) does not store any explanation for \( A_{o(j)} \) at the time it computes \( TV \), \( A_i \) assumes that \( tv^j \) is equal to \( d_{o(j)}^0 \geq 1 \). Otherwise, \( tv^j \) is equal to \( rhs(e_{o(j)}) \), where \( e_{o(j)} \) was either already stored by \( A_i \) or generated when calling \( \text{chooseVariableOrder} \). Now, we know that every explanation \( e_k \) stored by \( A_i \) has \( rhs(e_k) \geq 1 \) and we know that \( \text{chooseVariableOrder} \) cannot generate an explanation \( e'_k \) with \( rhs(e'_k) < rhs(e_k) - 1 \), where \( e_k \) was the explanation stored by

11
Therefore, we are guaranteed that $TV$ is such that $tv_j \geq 0, \forall j \in 1..n$. □

**Theorem 4** The algorithm Agile-ABT terminates.

**Proof.** The termination value of any agent decreases lexicographically and does not stay indefinitely unchanged (lemma 1). A termination value $[tv^1, \ldots, tv^n]$ cannot decrease indefinitely because $\forall i \in \{1, \ldots, n\}$, we have $tv^i \geq 0$ (lemma 2). Hence the theorem. □

# 6 Experimental Results

We compared Agile-ABT to ABT, ABTDO, and ABTDO with retroactive heuristics. All experiments were performed on the DisChoco 2.0 [3] platform, in which agents are simulated by Java threads that communicate only through message passing. We evaluate the performance of the algorithms by communication load and computation effort. Communication load is measured by the total number of messages exchanged among agents during algorithm execution ($\#msg$), including termination detection (system messages). Computation effort is measured by an adaptation of the number of non-concurrent constraint checks ($\#nccc$) [11] where we also count nogood checks to be closer to the actual computational effort.

For ABT, we implemented the standard version where we use counters for tagging assignments. For ABTDO [12], we implemented the best version, using the nogood-triggered heuristic where the receiver of a nogood moves the sender to be in front of all other lower priority agents (denoted by ABTDO-ng). For ABTDO with retroactive heuristics [13], we implemented the best version, in which a nogood generator moves itself to be in a higher position between the last and the second last agents in the generated nogood. However, it moves before an agent only if its current domain is smaller than the domain of that agent (denoted by ABTDO-Retro).

**Uniform binary random DisCSPs**

The algorithms are tested on uniform binary random DisCSPs that are characterized by $(n, d, p_1, p_2)$, where $n$ is the number of agents/variables, $d$ the number of values per variable, $p_1$ the network connectivity defined as the ratio of existing binary constraints, and $p_2$ the constraint tightness defined as the ratio of forbidden value pairs. We solved instances of two classes of problems: sparse problems $(20, 10, 0.2, p_2)$ and dense problems $(20, 10, 0.7, p_2)$. We vary the tightness $p_2$ from 0.1 to 0.9 by steps of 0.1. For each pair of fixed density and tightness $(p_1, p_2)$ we generated 25 instances, solved 4 times each. We report average over the 100 runs.

---

2. There are some discrepancies between the results reported in [13] and our version. This could be due to a bug that we fixed to ensure that ABTDO-ng and ABTDO-Retro actually terminate. You can see Appendix A and Appendix B for more details.
Figure 3 presents the results on the sparse instances ($p_1 = 0.2$). In terms of computational effort ($\#ncccs$) (left of Figure 3), ABT is the less efficient algorithm. ABTDO-ng improves ABT by a large scale and ABTDO-Retro is more efficient than ABTDO-ng. These findings are similar to those reported in [13]. Agile-ABT outperforms all these algorithms, suggesting that on sparse problems, the more sophisticated the algorithm is, the better it is. Regarding the number of exchanged messages ($\#msg$) (right of Figure 3), the faster resolution may not translate in an overall communication load reduction. ABT requires less messages than ABTDO-ng and ABTDO-Retro. On the contrary, Agile-ABT is the algorithm that requires the smallest number of messages despite its extra messages sent by agents to notify the others of a new ordering. This is not only because Agile-ABT terminates faster than the other algorithms (see $\#ncccs$).
A second reason is that Agile-ABT is more parsimonious than ABTDO algorithms in proposing new orders. Termination values seem to focus changes on those which will pay off.

Figure 4: Total $\#msg$ exchanged and $\#ncccs$ performed on dense problems ($p_1 = 0.7$).

Figure 4 presents the results on the dense instances ($p_1 = 0.7$). Some differences appear compared to sparse problems. Concerning $\#ncccs$ (left of Figure 4), ABTDO algorithms deteriorate compared to ABT. However, Agile-ABT still outperforms all these algorithms. Regarding communication load ($\#msg$) (right of Figure 4), ABTDO-ng and ABTDO-Retro show the same bad performance as in sparse problems. Agile-ABT shows similar communication load as ABT. This confirms its good behavior observed on sparse problems.
Distributed sensor-mobile problems

The distributed sensor-mobile problem [1] is a benchmark based on a real distributed problem. It consists of \( n \) sensors that track \( m \) mobiles. Each mobile must be tracked by 3 sensors. Each sensor can track at most one mobile. A solution must satisfy visibility and compatibility constraints. The visibility constraint defines the set of sensors that are visible to each mobile. The compatibility constraint defines the compatibility among sensors. We encode SensorDCSP in DisCSP as follows. Each agent represents one mobile. There are three different variables per agent, one for each sensor that we need to allocate to the corresponding mobile. The value domain of each variable is the set of sensors that can detect the corresponding mobile. The intra-agent constraints between the variables of one agent (mobile) specify that the three sensors assigned to the mobile must be distinct and pair-wise compatible. The inter-agent constraints between the variables of different agents specify that a given sensor can be selected by at most one agent. In our implementation of the DisCSP algorithms, this encoding is translated to an equivalent formulation where we have three virtual agents for every real agent, each virtual agent handling a single variable. Problems are characterized by \( \langle n, m, p_c, p_v \rangle \), where \( n \) is the number of sensors, \( m \) is the number of mobiles, \( p_c \) is the probability that two sensors are compatible and \( p_v \) is the probability that a sensor is visible to a mobile. We present results for class \( \langle 25, 5, 0.4, p_v \rangle \) where we vary \( p_v \) from 0.1 to 0.9 by steps of 0.1. Again, for each \( p_v \) we generated 25 instances, solved 4 times each one and averaged over the 100 runs. The results are shown in Figure 5.

When comparing the speed-up of algorithms (left of Figure 5), Agile-ABT is slightly dominated by ABT and ABTDO-ng in the interval \([0.3 \ 0.5]\), while outside of this interval, Agile-ABT outperforms all the algorithms. Nonetheless, the performance of ABT and ABTDO-ng dramatically deteriorate in the interval \([0.1 \ 0.3]\). Concerning communication load (right of Figure 5), as opposed to other dynamic ordering algorithm, Agile-ABT is always better than or as good as standard ABT.

Discussion

From the experiments above we can conclude that Agile-ABT outperforms other algorithms in terms of computation effort (\#necce) when solving random DisCSP problem. On structured problems (SensorDCSP), our results suggest that Agile-ABT is more robust than other algorithms whose performance is sensitive to the type of problems solved. Concerning communication load (\#msg), Agile-ABT is more robust than other versions of ABT with dynamic agent ordering. As opposed to them, it is always better than or as good as standard ABT on difficult problems.

At first sight, Agile-ABT seems to need less messages than other algorithms but these messages are longer than messages sent by other algorithms. One could object that for Agile-ABT, counting the number of exchanged messages is biased. However, counting the number of exchanged messages would be biased only if \#msg was smaller than the number of physically exchanged messages (going out from the network card). Now, in our experiments, they are the same. The International Organization for Standardization (ISO) has designed the Open Systems Interconnection (OSI) model to standardize networking. TCP and UDP are the principal Transport Layer protocols
using OSI model. The internet protocols IPv4 (http://tools.ietf.org/html/rfc791) and IPv6 (http://tools.ietf.org/html/rfc2460) specify the minimum datagram size that we are guaranteed to send without fragmentation of a message (in one physical message). This is 568 bytes for IPv4 and 1,272 bytes for IPv6 when using either TCP or UDP (UDP is 8 bytes less than TCP, see RFC-768 –http://tools.ietf.org/html/rfc768).

Figure 6 shows the size of the longest message sent by each algorithm on our random and sensor problems. It is clear that Agile-ABT requires lengthy messages compared to other algorithms. However, the longest message sent is always less than 568 bytes (in the worst case it is less than 350, see Figure 6(b)). In our implementation we do not proceed any message compression that would be a solution if the number of variables (n) was very large. Still, if n was so large that even the compression pro-

(b) dense problems ($p_1 = 0.7$)

(c) sensor-mobile problems where $p_c = 0.4$

Figure 6: Maximum message size in bytes.
tocol in the OSI model is not sufficient to fit one Agile-ABT message in one physical message, we believe that on such large problems, the exponential trend of the improvement of Agile-ABT would compensate by far for the linear overhead due to message splitting.

7 Conclusion

We have proposed Agile-ABT, an algorithm that is able to change the ordering of agents more agilely than all previous approaches. Thanks to the original concept of termination value, Agile-ABT is able to choose a backtracking target that is not necessarily the agent with the current lowest priority within the conflicting agents. Furthermore, the ordering of agents appearing before the backtracking target can be changed. These interesting features are unusual for an algorithm with polynomial space complexity. Our experiments confirm the significance of these features.

Appendices

A Appendix A: Why ABTDO is not correct

A.1 Preliminaries

We will show that ABTDO [12] is not correct. To this end, we first recall some features of this algorithm that we will need to build a counterexample:

- An agent $A_i$ can propose a new order each time it replaces its assignment. In the new order, only the positions of the agents that have lower priority than $A_i$ can be modified. However, these agents can not become higher than $A_i$.
- A nogood is a tuple of inconsistent assignments. An agent accepts a nogood if it contains no obsolete assignment. When an agent receives a new order that is more up to date than its current order, it removes the nogoods that are no longer valid according to the received order. A nogood message, contains in addition of the nogood itself, the identity of the agent that sent the nogood.
- An agent $A_i$ can sometimes mistakenly receive a nogood that contains some agents that have lower priority than itself. When this occurs, $A_i$ sends this nogood to the agent that has the lowest priority according to its current order. It will be specified in this message that the sender is $A_i$.

For ordering variables in ABTDO, Zivan and Meisels introduced in [12] three different heuristics. Among them, the Nogood-Triggered is the most efficient. In this heuristic, an agent $A_i$ can change the order only after receiving a nogood eliminating its current assignment. When this occurs, $A_i$ changes the order by placing the sender just after itself. In this note, we focus on ABTDO combined with the Nogood-Triggered heuristic (noted by ABTDO-ng).

A.2 Why the proof of ABTDO does not hold

To prove that ABTDO is correct, one needs to prove that it is sound, complete and that it terminates. The soundness of ABTDO is inherited from ABT. ABTDO is complete since an empty nogood can not be derived if a solution exists. To prove that ABTDO terminates, Zivan and Meisels first established two facts:

**Lemma 3** The highest priority agent in the initial order remains the highest priority agent in all proposed orders.

**Lemma 4** When the highest priority agent proposes a new order, it is more up to date than all previous orders.

Given these facts, Zivan and Meisels use induction on the number of agents in the DisCSP to prove that the algorithm terminates. For a single agent this property is verified. Assume now that this property is satisfied for any $k < n$. So this property is
satisfied for \( n - 1 \). Now, consider a DisCSP with \( n \) agents where \( A_1 \) is the highest priority agent. The position of \( A_1 \) will never be changed (lemma 3). When \( A_1 \) instantiates its value, it chooses a new order and sends it to all other agents. Now consider the DisCSP formed by the \( n - 1 \) lower priority agents. The initial order of this DisCSP is the order sent by \( A_1 \). According to Zivan and Meisels (2006), since the algorithm terminates for \( n - 1 \) agents, \( A_1 \) will continue to receive nogoods until the inconsistency is verified by ABTDO-ng as it was presented in [12] and the algorithm may fall into an infinite loop.

Note: In the following counterexample, any agent that proposes a new order already knows the most up-to-date order generated so far. Therefore, when an agent proposes a new order, this order is more up to date than all the orders generated so far.

### A.3 A counterexample

Let us consider a DisCSP instance with 5 agents \( \mathcal{A} = \{ A_1, A_2, A_3, A_4, A_5 \} \) where \( D(x_1) = D(x_4) = D(x_5) = \{1, 2\} \) and \( D(x_2) = D(x_3) = \{1, 2, 3\} \). The constraints of the instance are:

\[
\begin{align*}
c_{12} : (x_1, x_3) &\not\in \{(1, 1), (1, 2), (1, 3)\}; \\
c_{23} : (x_2, x_3) &\not\in \{(3, 3)\}; \\
c_{24} : (x_2, x_4) &\not\in \{(1, 1), (2, 1)\}; \\
c_{25} : (x_2, x_5) &\not\in \{(1, 1), (2, 1)\}; \\
c_{34} : (x_3, x_4) &\not\in \{(1, 2), (2, 2)\}; \\
c_{35} : (x_3, x_5) &\not\in \{(1, 2), (2, 2)\}.
\end{align*}
\]

**Step 1:**

\( o_1 = [A_1, A_2, A_3, A_4, A_5] \) where \( x_1 = 1, x_2 = 1, x_3 = 1, x_4 = 1 \) and \( x_5 = 1 \).

All agents instantiate theirs variables to the first value in their domains and send **ok**? messages to their neighbours.

After receiving the assignment \( (x_1 = 1) \), \( A_3 \) generates the nogood \( ng_1 : \neg(x_1 = 1) \) and sends it to \( A_1 \). \( A_3 \) removes \( x_1 = 1 \) from its AgentView and instantiates its variable to 1. It sends its current value in **ok**? \( (x_3 = 1) \) messages to all its neighbours including \( A_2 \).

After receiving \( ng_1 \), \( A_1 \) replaces its assignment and proposes a new order \( o_2 \) where \( A_3 \) is placed in the second position: \( o_2 = [A_1, A_3, A_2, A_4, A_5] \). \( A_1 \) sends \( o_2 \) to all other agents \( A_3, A_2, A_4 \) and \( A_5 \). The current assignment of \( A_1 \) is \( x_1 = 2 \).

**Step 2:**

\( A_2 \) and \( A_3 \) have received \( o_2 = [A_1, A_3, A_2, A_4, A_5] \).

\( A_2 \) receives the new assignment of \( A_3 \) \( (x_3 = 1) \).
Step 3:

$A_4$ has received the new assignment of $A_3$ but it has not yet received $o_2$. $A_4$ generates $ng_2 : \neg(x_2 = 1 \land x_3 = 1)$ and sends it to $A_3$. Since $A_2$ has lower priority than $A_3$ in $o_2$, $A_3$ sends $ng_2$ to $A_2$.

$A_2$ accepts $ng_2$ since it is coherent with its AgentView. $A_2$ replaces its current value with 2 and proposes a new order $o_3$ where $A_3$ is placed immediately after $A_2$: $o_3 = [A_1, A_2, A_3, A_4, A_5]$. The order $o_3$ is sent to all agents that has lower priority than $A_2$ in $o_3$ ($A_3, A_4$ and $A_5$).

$A_2$ removes $ng_2$ from its nogood-Store since it is no longer valid according to $o_3$. $A_2$ sends an ok? ($x_2 = 1$) message to all its neighbours including $A_3$.

Step 4:

$A_2$ has received $o_3 = [A_1, A_2, A_3, A_4, A_5]$ and the ok? ($x_2 = 1$) message sent by $A_2$. $A_3$ has received the new assignment of $A_2$.

$A_5$ has not yet received $o_3$. Until now, the order known by $A_5$ is $o_2 = [A_1, A_3, A_2, A_4, A_5]$.

$A_5$ generates a new nogood $ng_3 : \neg(x_3 = 1 \land x_2 = 2)$ and sends it to $A_2$.

When receiving $ng_3$, $A_2$ sends it to $A_3$ since it has the lowest priority according to $o_3$. $A_3$ accepts $ng_3$ since it is coherent with its AgentView. Because of $ng_3$, $A_3$ replaces its current assignment with 2 and proposes a new order $o_4$ where $A_2$ is placed immediately after $A_3$: $o_4 = [A_1, A_3, A_2, A_4, A_5]$. The order $o_4$ is sent to all agents that has lower priority than $A_3$ in $o_4$ ($A_2, A_4$ and $A_5$). Now $ng_3$ is removed from the nogood-Store of $A_3$ since it is no longer valid according to $o_4$.

$A_3$ sends an ok? ($x_3 = 2$) message to all its neighbours.

Step 5:

$A_2$ has received $o_4 = [A_1, A_3, A_2, A_4, A_5]$ and the ok? ($x_3 = 2$) message sent by $A_3$. $A_4$ has received the new assignment of $A_3$.

$A_4$ has not yet received $o_4$. Until now, the order known by $A_4$ is $o_3 = [A_1, A_2, A_3, A_4, A_5]$.

$A_4$ generates a new nogood $ng_4 : \neg(x_3 = 2 \land x_2 = 2)$ and sends it to $A_3$.

When receiving $ng_4$, $A_3$ sends it to $A_2$ since $A_2$ the lowest priority according to $o_4$. $A_2$ accepts $ng_4$ since it is coherent with its AgentView. Because of $ng_4$, $A_2$ replaces its current assignment with 1 and proposes a new order $o_5$ where $A_3$ is placed immediately after $A_2$: $o_5 = [A_1, A_2, A_3, A_4, A_5]$. The order $o_5$ is sent to all agents that has lower priority than $A_2$ in $o_5$, i.e $A_3, A_4$ and $A_5$.

$A_2$ removes $ng_4$ from its nogood-Store since it is no longer valid according to $o_5$. $A_2$ sends an ok? ($x_2 = 1$) message to all its neighbours.
When receiving $ng_5$, $A_2$ sends it to $A_3$ since $A_3$ is the lowest priority according to $o_5$. $A_3$ accepts $ng_5$ since it is coherent with its AgentView. Because of $ng_5$, $A_3$ replaces its current assignment with 1 and proposes a new order $o_6$ where $A_2$ is placed immediately after $A_3$: $o_6 = [A_1, A_3, A_2, A_4, A_5]$. The order $o_6$ is sent to all agents that has lower priority than $A_3$ in $o_6$ ($A_2$, $A_4$ and $A_5$).

$A_3$ removes $ng_5$ from its nogood-Store since it is no longer valid according to $o_6$. $A_3$ sends an $ok?$ ($x_3 = 1$) message to all its neighbours.

Hence, we come back to the order $o_2$ ($o_6 = o_2$) without performing any progress since all nogoods have been removed. Thus, ABTDO-ng may not terminate.

### A.4 How to ensure that ABTDO actually terminate

The concern with ABTDO-ng is that an agent $A_i$ that replaces its assignment sends $ok?$ messages before sending order messages. As a result, another agent $A_k$ that has not yet received the order message, can use the assignment contained in the $ok?$ message to generate a nogood and therefore to send this nogood to the wrong agent. To remedy this, in our implementation, in addition to the value taken by the agent’s variable, an $ok?$ message also contains the order.
Appendix B: Retroactive Dynamic Ordering for Asynchronous Backtracking algorithm may not terminate

B.1 Preliminaries

Zivan and Meisels (2006) proposed Dynamic Ordering for Asynchronous Backtracking (ABTDO). In this algorithm, when an agent assigns a value to its variable, it can reorder lower priority agents. Each agent in ABTDO holds a current order which is an ordered list of pairs. Every pair includes the ID of one of the agents and a counter. The counters attached to each agent ID in the order list form a time-stamp. Initially, all time-stamp counters are zero and all agents start with the same order. Each agent that proposes a new order increments its counter by one and sets to zero counters of all lower priority agents (the counters of higher priority agents are not modified). When comparing two orders, the most up-to-date is the one with the lexicographically larger time-stamp. In other words, the most up-to-date order is the one for which the first different counter is larger.

A new kind of ordering heuristics for ABTDO is presented in [13]. These heuristics, called retroactive heuristics, enable the generator of the nogood to be moved to a higher position than that of the target of the backtrack. In [13], ties which could not have been generated in standard ABTDO, are broken using the agents indexes. In other words, when two contradictory orders have the same time-stamp, the most up-to-date order is the one for which the index of the first different agent is smaller. The degree of flexibility of these heuristics is dependent on the size of the nogood storage capacity, which is predefined. Agents are limited to store nogoods smaller or equal to a predefined size $K$. The space complexity of the agents is thus exponential in $K$.

However, the best heuristic proposed in [13] does not require this exponential storage of nogoods. In this heuristic called ABTDO-Retro-MinDom, agents that generate a nogood are placed in the new order between the last and the second last agents in the generated nogood. However, agents are moved to a higher position only if their domain is smaller than that of the agents they pass on the way up. Otherwise, the generator of the nogood is placed right after backtracking target.

B.2 ABTDO-Retro-MinDom may not terminate: a counterexample

We will now show that ABTDO-Retro-MinDom may not terminate. To this end, consider a DisCSP of 5 agents $\{A_1, A_2, A_3, A_4, A_5\}$. We assume that, initially, all agents store the same order $o_1 = [A_1, A_5, A_4, A_2, A_3]$ with $s_1 = [0, 0, 0, 0, 0]$. We assume that: $D(x_2) = D(x_3) = D(x_4) = \{6, 7\}$ and $D(x_1) = D(x_5) = \{1, 2, 3, 4, 5\}$.

The constraints are:

- $c_{12}: (x_1, x_2) \not\in \{(1, 6), (1, 7)\}$
- $c_{13}: (x_1, x_3) \not\in \{(2, 6), (2, 7)\}$
- $c_{14}: (x_1, x_4) \not\in \{(1, 6), (1, 7)\}$
- $c_{24}: (x_2, x_4) \not\in \{(6, 6), (7, 7)\}$.
\[c_{35} : (x_1, x_5) \not\in \{(6, 4), (6, 3), (7, 5)\}.\]

In the following we give a possible execution of ABTDO-Retro-MinDom.

\(t_0\): All agents assigns their variables to the first values in their domains and send \textit{ok?} messages to their neighbours.

\(t_1\): \(A_4\) receives the first \textit{ok?} \((x_1 = 1)\) message sent by \(A_1\) and generates a nogood \(n_{g_1} : \neg(x_1 = 1)\). Then, it proposes a new order \(o_2 = [A_4, A_1, A_5, A_2, A_3]\) with \(s_2 = [1, 0, 0, 0, 0]\). Afterwards, it assigns the value 6 to its variable and sends \textit{ok?} \((x_4 = 6)\) message to all its neighbours (including \(A_2\)).

\(t_2\): \(A_3\) receives \(o_2 = [A_4, A_1, A_5, A_2, A_3]\) and deletes \(o_1\) since \(o_2\) is more up-to-date;
\(A_1\) receives the nogood sent by \(A_4\), it replaces its assignment by 2 and sends an \textit{ok?} \((x_1 = 2)\) message to all its neighbours.

\(t_3\): \(A_2\) has not yet received \(o_2\) and the new assignment of \(A_1\). \(A_2\) generates the same nogood as \(n_{g_1}, n_{g_2} : \neg(x_1 = 1)\) and proposes a new order \(o_3 = [A_2, A_1, A_5, A_4, A_3]\) with \(s_3 = [1, 0, 0, 0, 0]\); Afterwards, it assigns the value 6 to its variable and sends \textit{ok?} \((x_2 = 6)\) message to all its neighbours (including \(A_4\)).

\(t_4\): \(A_4\) receives the new assignment of \(A_2\) (i.e. \(x_4 = 6\)) and \(o_3 = [A_2, A_1, A_5, A_4, A_3]\). Afterwards, it discards \(o_2\) since \(o_3\) is more up-to-date; Then, \(A_4\) tries to satisfy \(c_{24}\) because \(A_2\) has a higher priority according to \(o_3\). Hence, \(A_4\) replaces its current assignment (i.e \(x_4 = 6\)) by \(x_4 = 7\) and sends an \textit{ok?} \((x_4 = 7)\) message to all its neighbours (including \(A_4\)).

\(t_5\): After receiving the new assignment of \(A_1\) (i.e \(x_1 = 2\)) and before receiving \(o_3 = [A_2, A_1, A_5, A_4, A_3]\), \(A_2\) generates a nogood \(n_{g_3} : \neg(x_1 = 1)\) and proposes a new order \(o_4 = [A_4, A_3, A_1, A_5, A_2]\) with \(s_4 = [1, 1, 0, 0, 0]\); The order \(o_4\) is more up-to-date than \(o_3\). Since in ABTDO, an agent sends the new order only to lower priority agents, \(A_3\) will not send \(o_4\) to \(A_4\) because it is a higher priority agent.

\(t_6\): \(A_2\) receives \(o_4\) but it has not yet received the new assignment of \(A_4\). Then, it tries to satisfy \(c_{24}\) because \(A_4\) has a higher priority according to its current order \(o_4\). Hence, \(A_2\) replaces its current assignment (i.e \(x_2 = 6\)) by \(x_2 = 7\) and sends an \textit{ok?} \((x_2 = 7)\) message to all its neighbours (including \(A_4\)).

\(t > t_6\): ABTDO-Retro-MinDom will not terminate if \(A_2\) and \(A_4\) always change their values simultaneously.
B.3 How to ensure that ABTDO-Retro-MinDom actually terminate

To ensure that ABTDO-Retro-MinDom actually terminate, we have to simply make sure that after a finite time, all agents that share a constraint agree on the order. A simple way to this is to send the order in the ok? messages (ok? messages are sent to all neighbours). Of course, an agent that proposes a new order should also send order messages to lower priority agents that not share a constraint with it.
