Abstract—SUM queries are crucial for many applications that need to deal with uncertain data. In this paper, we are interested in the queries, called ALL\_SUM, that return all possible sum values and their probabilities. In general, there is no efficient solution for the problem of evaluating ALL\_SUM queries. But, for many practical applications, where aggregate values are small integers or real numbers with small precision, it is possible to develop efficient solutions. In this paper, based on a recursive approach, we propose a new solution for this problem. We implemented our solution and conducted an extensive experimental evaluation over synthetic and real-world data sets; the results show its effectiveness.

Index Terms—Database Management, Systems, Query processing.

1 INTRODUCTION

Aggregate (or \texttt{agg} for short) queries, in particular SUM queries, are crucial for many applications that need to deal with uncertain data [14][20][28]. Let us give two motivating examples from the medical and environmental domains.

Example 1: Reducing the usage of pesticides. Consider a plant monitoring application on which we are working with scientists in the field of agronomy. The objective is to observe the development of diseases and insect attacks in the agricultural farms by using sensors, aiming at using pesticides only when necessary. Sensors periodically send to a central system their data about different measures such as the plants contamination level (an integer in [0..10]), temperature, moisture level, etc. However, the data sent by sensors are not 100\% certain. The main reasons for the uncertainty are the effect of climate events on sensors, e.g. rain, unreliability of the data transmission media, etc. The people from the field of agronomy with which we had discussions use some rules to define a degree of certainty for each received data. A decision support system will analyze the sent data, and trigger a pesticide treatment when the sum of contamination since the last treatment is higher than a threshold with a high probability. An important query for the decision support system is “given a contamination threshold \( s \), what is the cumulative probability that the contamination sum be higher than \( s \)\?”. The treatment starts when the query result is higher than a predefined probability.

Example 2: Remote health monitoring. As another example, we can mention a medical center that monitors key biological parameters of remote patients at their...

possible worlds, i.e. the possible database instances, their world. In this example, there are 8 possible worlds and four possible sum values, i.e. 0 to 3.

Figure 1 is \{(3, 0.40), (2, 0.10), (1, 0.40), (0, 0.10)\}, i.e. for ALL_SUM (required nurses) for the database shown in Figure 1, by using the results of ALL_SUM, the cumulative distribution function of sum values over the data of Figure 1 is depicted.

A naïve algorithm for evaluating ALL_SUM queries is to enumerate all possible worlds, compute sum in each world, and return the possible sum values and their aggregated probability. However, this algorithm is exponential in the number of uncertain tuples.

In this paper, we deal with ALL_SUM queries and propose pseudo-polynomial algorithms that are efficient in many practical applications, e.g. when the aggr attribute values are small integers or real numbers with small precision, i.e. small number of digits after decimal point. These cases cover many practical aggregate attributes, e.g. temperature, blood pressure, needed human resources per patient in medical applications. To our knowledge, this is the first proposal of an efficient solution for returning the exact results of ALL_SUM queries.

1.1 Contributions

In this paper, we propose a complete solution to the problem of evaluating SUM queries over probabilistic data:

- We first propose a new recursive approach for evaluating ALL_SUM queries, where we compute the sum probabilities in a database based on the probabilities in smaller databases.

- Based on this recursive approach, we propose a pseudo-polynomial algorithm, called DP_PSUM that efficiently evaluates ALL_SUM queries for the applications where the aggr attribute values are small integers or real numbers with small precision. For example, in the case of positive integer aggr values, the execution time of DP_PSUM is \(O(n \times \text{avg})\) where \(n\) is the number of tuples and \(\text{avg}\) is the average of the aggr values.

- Based on this recursive approach, we propose an algorithm, called Q_PSUM, which is polynomial in the number of SUM results.

- We validated our algorithms through implementation over synthetic and real-world data sets; the results show the effectiveness of our solution.

The rest of the paper is organized as follows. In Section 2, we present the probabilistic data models, which we consider and define formally the problem we address. In Sections 3 and 4, we describe our Q_PSUM and DP_PSUM algorithms for evaluating ALL_SUM queries under a simple and frequently used model. In Sections 5 and 6, we extend our solution for a more complex model with some correlations. We also extend our solution for evaluating COUNT queries in Section 6. In Section 7, we report on our experimental validation over synthetic and real-world data sets. Section 8 discusses related work. Section 9 concludes and gives some directions for future work.

2 Problem Definition

In this section, we first introduce the probabilistic data

homes, e.g. using sensors in their bodies. The sensors periodically send to the center the patients’ health data, e.g. blood pressure, hydration levels, thermal signals, etc. For high availability, there are two or more sensors for each biological parameter. However, the data sent by sensors are uncertain, and the sensors that monitor the same parameter may send inconsistent values. There are approaches to estimate a confidence value for the data sent by each sensor, e.g. based on their precision [15]. According to the data sent by the sensors, the medical application computes the number of required human resources, e.g. nurses, and equipments for each patient. Figure 1 shows an example table of this application. The table shows the number of required nurses for each patient. This system needs to have sufficient human resources in order to assure its services with a high probability. One important query for the system is “given a threshold \(s\), return the cumulative probability that the sum of required nurses be at most \(s\)”. Based on the data in Figure 1, we show in Figure 2 the possible worlds, i.e. the possible database instances, their probabilities, and the result of the SUM query in each world. In this example, there are 8 possible worlds and four possible sum values, i.e. 0 to 3.

In this paper, we are interested in the queries that return all possible sum values and their probabilities. This kind of query, which we call ALL_SUM, is also known as sum probability distribution. For instance, the result of ALL_SUM (required nurses) for the database shown in Figure 1 is \((3, 0.40), (2, 0.10), (1, 0.40), (0, 0.10)\), i.e. for each possible SUM result, we return the result and the probability of the worlds in which this result appears. For instance, the result sum=3 appears in the worlds \(w₁\) and \(w₃\), so its probability is equal to \(P(w₁) + P(w₃) = 0.16 + 0.24 = 0.40\).

By using the results of ALL_SUM, we can generate the cumulative distribution functions, which are important for many domains, e.g. scientific studies. For example to answer the query stated in Erreur ! Argument de commutateur inconnu., we need to be able to compute the cumulative probability for possible contamination sums that are higher than the threshold \(s\). Similarly, for the query described in Erreur ! Argument de commutateur inconnu., we should compute the cumulative probability when the sum value is lower than or equal to the threshold. In
models that we consider. Then, we formally define the problem that we address.

### 2.1 Probabilistic Models

The two main models, which are frequently used in our community, are the tuple-level and attribute-level models [9]. These models, which we consider in this paper, are defined as follows.

**Tuple-level model.** In this model, each uncertain table \( T \) has an attribute that indicates the membership probability (also called existence probability) of each tuple in \( T \), i.e. the probability that the tuple appears in a possible world. In this paper, the membership probability of a tuple \( t_i \) is denoted by \( p(t_i) \). Thus, the probability that \( t_i \) does not appear in a random possible world is \( 1 - p(t_i) \). The database shown in Figure 4.a is under tuple-level model.

**Attribute-level model.** In this model, each uncertain tuple \( t_i \) has at least one uncertain attribute, e.g. \( a \), and the value of \( a \) in \( t_i \) is chosen by a random variable \( X \). We assume that \( X \) has a discrete probability density function (pdf). This is a realistic assumption for many applications [9], e.g. sensor readings [12][22]. The values of \( a \) in \( t_i \) are \( m \) values \( v_{1,i}, \ldots, v_{m,i} \) with probabilities \( p_{1,i}, \ldots, p_{m,i} \) respectively (see Figure 4.b). Note that for each tuple we may have a different pdf.

The tuples of the database may be independent or correlated. In this paper, we first present our algorithms for databases in which tuples are independent. We extend our algorithms for correlated databases in Section 6.1.

### 2.2 Problem Definition

**ALL_SUM query is defined as follows.**

**Definition 1: ALL_SUM query.** It returns all possible sum results together with their probability. In other words, for each possible sum value, ALL_SUM returns the cumulative probability of the worlds where the value appears as a result of the query.

Let us now formally define ALL_SUM queries. Let \( D \) be a given uncertain database, \( W \) the set of its possible worlds, and \( P(w) \) the probability of a possible world \( w \in W \). Let \( Q \) be a given agg. query, \( f \) the agg. function stated in \( Q \) (i.e. \( \text{SUM} \)), \( f(w) \) the result of executing \( Q \) in a world \( w \in W \), and \( V_D \) the set of all possible results of executing \( Q \) over \( D \), i.e. \( V_D = \{ p_1 / \exists w \in W \land f(w) = v \} \). The cumulative probability of having a value \( v \) as the result of \( Q \) over \( D \), denoted as \( P(v, Q, D) \), is computed as follows:

\[
P(v, Q, D) = \sum_{w \in W \land f(w) = v} P(w)
\]

Our objective in this paper is to return the results of ALL_SUM as follows:

\[
\text{ALL}_\text{SUM}(Q, D) = \{ (v, p) / \forall v \in V_Q \land p = P(v, Q, D) \}
\]

### 3 ALL_SUM under Tuple-level Model

In this section, we propose an efficient solution for evaluating ALL_SUM queries. We first propose a new recursive approach for computing the results of ALL_SUM. Then, using the recursive approach we propose our Q_PSUM algorithm.

We assume that the database is under the tuple-level model defined in the previous section. Our solution is extended for the attribute-level model in Section 5. We adapt our solution to process COUNT queries in Section 6.3.

#### 3.1 Recursive Approach

We develop a recursive approach that produces the results of ALL_SUM queries in a database with \( n \) tuples based on the results in a database with \( n-1 \) tuples. The principle behind it is that the possible worlds of the database with \( n \) tuples can be constructed by adding / not adding the \( n \)th tuple to the possible worlds of the database with \( n-1 \) tuples.

Let DB\(^n\) be a database involving the tuples \( t_1, \ldots, t_n \) and \( ps(i,n) \) be the probability of having sum \( = i \) in DB\(^n\). We develop a recursive approach for computing ps\((i, n)\).
Algorithm PS(i, n)
Input:
 n : number of tuples;
t_1, …, t_n : the tuples of the database;
p(t) : a function that returns the probability of tuple t;
Output:
Probability of sum=i in a database containing t_1, …, t_n;
Begin
If (n > 1) then
    Return PS(i, n-1)×(1- p(t_n)) + PS(i - val(t_n), n-1)×p(t_n);
Else If ((n=1) and (i=val(t_1)) and (val(t_1) ≠ 0)) then
    Return p(t_1);
Else If ((n=1) and (i=0) and (val(t_1) ≠ 0)) then
    Return 1 - p(t_1);
Else
    Return 1;
End If
Else Return 0;
End;

Figure 6. Recursive algorithm for computing the probability of sum=i in a database containing t_1, …, t_n.

3.1.1 Base
Let us first consider the recursion base. Consider DB^1, i.e. the database that involves only tuple t_1. Let p(t_1) be the probability of t_1, and val(t_1) be the value of t_1 in aggr attribute. In DB^1, there are two worlds: 1) w_1=[][] in which t_1 does not exist, so its probability is (1-p(t_1)); 2) w_2=[t_1], in which t_1 exists, so the probability is p(t_1). In w_2, we have sum=0, and in w_1 we have sum= val(t_1). If val(t_1) = 0, then we always have sum=0 because in both w_1 and w_2, sum is zero. Thus, in DB^1, ps(i, 1) can be written as follows:

\[
\text{ps}(i, 1) = \begin{cases} 
  p(t_1) & \text{if } i = \text{val}(t_1) \text{ and } \text{val}(t_1) \neq 0 \\
  1 - p(t_1) & \text{if } i = 0 \text{ and } \text{val}(t_1) \neq 0 \\
  0 & \text{if } i = \text{val}(t_1) = 0 \quad (1) \\
  0 & \text{otherwise}
\end{cases}
\]

3.1.2 Recursion Step
Now consider DB^{n-1}, i.e. a database involving the tuples t_1, …, t_{n-1}. Let W^{n-1} be the set of possible worlds in DB^{n-1}.

We construct DB^n by adding t_n to DB^{n-1}. Notice that the set of possible worlds in DB^n, denoted by W^n, is constructed by adding / not adding the tuple t_n to each world of W^{n-1}. Thus, in W^n, there are two types of worlds (see Figure 5): 1) the worlds that do not contain t_n, denoted as W_1^n; 2) the worlds that contain t_n, denoted as W_2^n.

For each world w we W_1^n, we have the same world in DB^{n-1}, say w'. Let p(w) and p(w') be the probability of worlds w and w'. The probability of w, i.e. p(w), is equal to p(w')×(1 - p(t_n)), because t_n does not exist in w even though it is involved in the database. Thus, in W_1^n the sum values are the same as in DB^{n-1}, but the probability of sum=i in W_1^n is equal to the probability of having sum=i in DB^{n-1} multiplied by the probability of non-existence of t_n.

In W_2^n, the probability of sum=i is \( ps(i, n-1)\times(1 - p(t_n)) \) (2)

Let us now consider W_2^n. The worlds involved in W_2^n are constructed by adding t_n to each world of DB^{n-1}. Thus, for each sum value equal to i in DB^{n-1} we have a sum value equal to (i + val(t_n)) in W_2^n, where val(t_n) is the value of aggr attribute in t_n. Therefore, the probability of sum=i + val(t_n) in W_2^n is equal to the probability of sum=i in DB^{n-1} multiplied by the existence probability of t_n. In other words, we have:

In W_2^n: (probability of sum=i) = \( ps(i, n-1)\times p(t_n) \) (3)

The probability of sum=i in DB^n is equal to the probability of sum=i in W_1^n plus the probability of sum=i in W_2^n. Thus, using the Equations 2 and 3, and using the base of the recursion, i.e. Equation 1, we obtain the following recursive formula for the probability of sum=i in DB^n, i.e. ps(i, n):

\[
ps(i, n) = \begin{cases} 
  ps(i, n-1)\times(1 - p(t_n)) + ps(i-\text{val}(t_n), n-1)\times p(t_n) & \text{if } n > 1 \\
  1 - p(t_n) & \text{if } n = 1 \text{ and } i = 0 \text{ and } \text{val}(t_n) \neq 0 \\
  p(t_n) & \text{if } n = 1 \text{ and } i = \text{val}(t_n) \text{ and } \text{val}(t_n) \neq 0 \\
  1 & \text{if } n = 1 \text{ and } i = \text{val}(t_n) = 0 \\
  0 & \text{otherwise}
\end{cases}
\]

Based on the above recursive formula, we can develop a recursive algorithm for computing the probability of sum=i in a database containing tuples t_1, …, t_n (see the pseudocode in Figure 6). However, the execution time of the algorithm is exponential in the number of uncertain tuples, i.e. due to the two recursive calls in the body of the algorithm.

3.2 Q_PSUM Algorithm
In this section, based on our recursive definition, we propose an algorithm, called Q_PSUM, whose execution time is \( O(n \times N) \) where n is the number of uncertain data, and N is the number of distinct sum values.

Q_PSUM uses a list for maintaining the computed possible sum values and their probabilities. It fills the list by starting with DB^n, i.e. a database containing only t_n, and then it gradually adds other tuples to the database and updates the list.

Let Q be a list of pairs (i, ps) such that i is a possible sum value and ps its probability. The Q_PSUM algorithm proceeds as follows (see the pseudocode in Appendix C).

It first initializes Q for DB^n by using the base of the recursive definition. If \( \text{val}(t_n) = 0 \), then it inserts \((0, 1)\) into Q, else it inserts \((0, 1 - p(t_n))\) and \((\text{val}(t_n), p(t_n))\). By inserting a pair to a list, we mean adding the pair to the end of the list.

Then, in a loop, for \( j = 2 \) to \( n \), the algorithm adds the tuples t_j to t_n to the database one by one, and updates the list by using two temporary lists Q_0 and Q_2 as follows. For
each tuple \( t_i \). Q_PREM removes the pairs involved in \( Q \) one by one from the head of the list, and for each pair \((i, ps)\) of \( Q \), it inserts \((i, ps×(1 - p(t_i)))\) into \( Q \) and \((i+val(t_i), ps×p(t_i))\) into \( Q_2 \). Then, it merges the pairs involved in \( Q_1 \) and \( Q_2 \) and inserts the merged results into \( Q \).

The merging is done on the sum values of the pairs. That means that for each pair \((i, ps)\) of \( Q \), if there is a pair \((i, ps)\) of \( Q_1 \) with the same sum value, then Q_PREM removes the pairs from \( Q_1 \) and \( Q_2 \) and inserts \((i, ps1 + ps2)\) into \( Q \). If there is \((i, ps)\) of \( Q_1 \) but there is no pair \((i, ps)\) of \( Q_2 \), then it simply removes the pair from \( Q_1 \) and inserts it to \( Q \).

Let us now analyze the complexity of Q_PREM. Let \( N \) be the number of possible (distinct) sum results. Suppose the lists are implemented using a structure such as linked list (with pointers to the head and tail of the list). The cost of inserting a pair to the list is \( \Theta(1) \), and merging two lists is done in \( O(N) \). For each tuple, at most \( N \) pairs are inserted to the lists \( Q_1 \) and \( Q_2 \), and this is done in \( O(N) \). The merging is done in \( O(N) \). There are \( n \) tuples in the database, thus the algorithm is executed in \( O(n \times N) \). The space complexity of the algorithm is \( O(N) \), i.e. the space needed for the lists.

4 DP_PSUM ALGORITHM

In this section, using the dynamic programming technique, we propose an efficient algorithm, called DP_PSUM, designed for the applications where aggr values are integer or real numbers with small precisions. It is usually much more efficient than the Q_PSUM algorithm (as shown by the performance evaluation results in Section 4.5).

Let us assume, for the moment, that the values of aggr attribute are positive integer numbers. In Section 4.3, we adapt our algorithm for real numbers with small precisions, and in Section 4.4, we deal with negative integer numbers.

4.1 Basic Algorithm

Let MaxSum be the maximum possible sum value, e.g. for positive aggr values MaxSum is the sum of all values. DP_PSUM uses a 2D matrix, say PS, with \((\text{MaxSum} + 1) \times n \) rows and \( n \) columns. DP_PSUM is executed on PS, and when it ends, each entry \( PS[i, j] \) contains the probability of \( sum=i \) in a database involving tuples \( t_1, \ldots, t_n \).

DP_PSUM proceeds in two steps as follows (the pseudocode is shown in Appendix C). In the first step, it initializes the first column of the matrix. This column represents the probability of sum values for a database involving only the tuple \( t_i \). DP_PSUM initializes this column using the base of our recursive formula (described in Equation 1) as follows. If \( val(t_i) = 0 \), then \( PS[0, 1] = 1 \). Otherwise, \( PS[0, 1] = (1 - p(t_i)) \) and \( PS[val(t_i), 1] = p(t_i) \). The other entries of the first column should be set to zero, i.e., \( PS[i, 1] = 0 \) if \( i \neq 0 \) and \( i \neq \text{val}(t_i) \).

In the second step, in a loop, DP_PSUM sets the values of each column \( j \) (for \( j = 2 \) to \( n \)) by using our recursive definition (i.e. Equation 4) and based on the values in column \( j-1 \) as follows:

\[
PS[i, j] = PS[i, j-1] \times (1 - p(t_j)) + PS[i - \text{val}(t_j), j-1] \times p(t_j)
\]

Notice that if \( (i < \text{val}(t_j)) \), then for the positive aggr values we have \( PS[i - \text{val}(t_j), j] = 0 \), i.e. because there is no possible sum value lower than zero. This is why, in the algorithm only if \( (i \geq \text{val}(t_j)) \), we consider \( PS[i - \text{val}(t_j), j] \) \( \times p(t_j) \) for computing \( PS[i, j] \).

Theorem 1. DP_PSUM works correctly if the database is under the tuple-level model, and the aggr attribute values are positive integers, and their sum is less than or equal to MaxSum.

Proof. Implied by using the recursive formula in Equation 4.

Let us now illustrate DB_PSUM using the following example.

Example 3. Figure 7.b shows the execution of DP_PSUM over the database shown in Figure 7.a. In the first column, we set the probability of sum values for DB', i.e. a database that only involves \( t_i \). Since the aggr value of \( t_1 \) is equal to 1 (see Figure 7.a), in DB' there are two possible sum values, sum=1 and sum=0 with probabilities 0.3 and \( (1 - 0.3) = 0.7 \) respectively. The probabilities in other columns, i.e. in \( 2^{nd} \) and \( 3^{rd} \), are computed using our recursive definition. After the execution of the algorithm, the \( 3^{rd} \) column involves the probability of sum values in the entire database. If we compute ALL_SUM by enumerating the possible worlds, we obtain the same results.

4.2 Complexity

Let us now discuss the complexity of DP_PSUM. The first step of DP_PSUM is done in \( O(\text{MaxSum}) \), and its second step in \( O(n \times \text{MaxSum}) \). Thus, the time complexity of DP_PSUM is \( O(n \times \text{MaxSum}) \), where \( n \) is the number of uncertain tuples and MaxSum the sum of the aggr values of all tuples. Let \( \text{avg} \) be the average value of aggr values of tuples, then we have \( \text{MaxSum} = n \times \text{avg} \). Thus, the complexity of DP_PSUM is \( O(n \times \text{avg}) \) where \( \text{avg} \) is the average of the aggr values in the database.

Notice that if \( \text{avg} \) is a small number compared to \( n \), then DP_PSUM is done in a time quadratic to the input. But, if \( \text{avg} \) is exponential in \( n \), then the execution time becomes exponential. Therefore, DP_PSUM is a pseudo polynomial algorithm.

The space requirement of DP_PSUM is equivalent to a matrix of \((\text{MaxSum} + 1) \times n \), thus the space complexity is \( O(n \times \text{avg}) \). In Section 4.2.1, we reduce the space complexity of DP_PSUM to \( O(n \times \text{avg}) \).

4.2.1 Reducing space complexity

In the basic algorithm of DP_PSUM, for computing each column of the matrix, we use only the data that are in the precedent column. This observation gave us the idea of using two arrays instead of a matrix for computing ALL_SUM results as follows. We use two arrays of size \((\text{MaxSum} + 1) \), e.g. \( ar_1 \) and \( ar_2 \). First, we initialize \( ar_1 \) using the recursion base (like the first step of the basic version). Then, for \( i = 2, \ldots, n \) steps, DP_PSUM fills \( ar_2 \) using the probabilities in \( ar_1 \) based on the recursion step, then it copies the data of \( ar_2 \) into \( ar_1 \), and starts the next
step. Instead of copying the data from \( ar_2 \) into \( ar_1 \), we can simply change the pointers of \( ar_1 \) to that of \( ar_2 \), and renew the memory of \( ar_2 \).

The space requirement of this version of DP_PSUM is \( O(\text{MaxSum}) \) which is equivalent to \( O(n \times \text{avg}) \) where \( \text{avg} \) is the average value of \( \text{aggr} \) values.

### 4.3 Supporting real attribute values with small precisions

In many applications that work with real numbers, the precision of values, i.e. the number of digits after decimal point, is small. For example, in medical applications the temperature of patients requires real values with one digit of precision. DP_PSUM can be adapted to work for those applications as follows. Let \( DB \) be the input database, and \( c \) be the number of precision digits in the \( \text{aggr} \) values. We generate a new database \( DB' \) as follows. For each tuple \( t \) in the input database \( DB \), we insert a tuple \( t' \) to \( DB' \) such that the \( \text{aggr} \) value of \( t' \), say \( v' \), is equal to the \( \text{aggr} \) value of \( t \), say \( v \), multiplied by \( 10^c \), i.e. \( v' = v \times 10^c \). Now, we are sure that the \( \text{aggr} \) values in \( DB' \) are integer, and we can apply the DP_PSUM algorithm on it. Then, for each \( \text{ALL\_SUM} \) result \((v', p)\) over \( DB' \), we return \((v' / 10^c, p)\) as a result of \( \text{ALL\_SUM} \) in \( DB' \).

The correctness of the above solution can be implied by the fact that, if we multiply all \( \text{aggr} \) values of a DB by a constant \( k \), then every possible sum result is multiplied by \( k \).

The time complexity of this version of DP_PSUM for \( \text{aggr} \) attribute values with \( c \) digits of precision is \( O(n \times \text{MaxSum} \times 10^c) \) which is equivalent to \( O(n \times \text{avg} \times 10^c) \) where \( \text{avg} \) is the average of the \( \text{aggr} \) attribute values. The space complexity is \( O(n \times \text{avg} \times 10^c) \).

### 4.4 Dealing with negative integer values

The basic version of DP_PSUM assumes integer values that are positive, i.e. \( \geq 0 \). This assumption can be relaxed as follows. Let \( \text{MinNeg} \) be the sum of all negative \( \text{aggr} \) values. Then, the possible sum values are integer values in \([\text{MinNeg} .. \text{MaxSum}] \) where \( \text{MaxSum} \) is the maximum possible sum value, i.e. the sum of positive \( \text{aggr} \) values. Thus, to support negative values, the size of the first dimension of the matrix should be modified to \( (\text{MaxSum} + 1 + |\text{MinNeg}|) \). In addition, the algorithm should scan the possible sum values from \( \text{MinNeg} \) to \( \text{MaxSum} \), instead of 0 to \( \text{MaxSum} \). Moreover, since the index in the matrix cannot be negative, we should shift the index of the first dimension by \( |\text{MinNeg}| \).

### 4.5 Leveraging GCD

For the case of integer \( \text{aggr} \) values, if the greatest common divisor (GDC) of the values is higher than 1, e.g. when the values are even, then we can significantly improve the performance of the DP_PSUM algorithm as follows. Let \( DB \) be the given database, and \( \text{g} \) be the GCD of the \( \text{aggr} \) values. We generate a new database \( DB' \) in which the tuples are the same as in \( DB \) except that the \( \text{aggr} \) values are divided by \( \text{g} \). Then, we apply DP_PSUM on \( DB' \), and for each sum result \((v', p)\), we return \((v' \times \text{g}, p)\) to the user.

In most cases, the GCD of \( \text{aggr} \) values is 1, so the above approach is not applicable. However, when we know that GCD is higher than one, using this approach can reduce the time and space complexities of DP_PSUM by an order of GCD, i.e. since the average of the \( \text{aggr} \) values in database \( DB' \) is divided by GCD. For example, if the \( \text{aggr} \) values in \( DB \) are \([10, 20, 30]\), then in the database \( DB' \) the \( \text{aggr} \) values are \([1, 2, 3]\), i.e. \( \text{GCD}=10 \). Since the average of \( \text{aggr} \) values is reduced by 10, the space and time complexity of the DP_PSUM algorithm will be reduced by an order of 10.

### 4.6 Skipping Zero Points

During execution of the basic version of our DP_PSUM algorithm, there are many cells (of the matrix) with zero points, i.e. zero probability values. Obviously, we do not need to read zero points because they cannot contribute to non-zero probability values. We can avoid accessing zero points using the following approach. Let \( L \) be a list that is initially set to zero. During the execution of the algorithm we add the index of non zero points to \( L \), and for filling each new column, we take into account only the cells whose indices are in \( L \).

This approach improves significantly the performance of DP_PSUM, in particular when the number of tuples is very small compared to the average of \( \text{aggr} \) values, i.e. \( \text{avg} \). For example, if there are only two tuples and \( \text{avg} \) is equal to 10, then each column of the matrix has about 20 cells. However, there are at most 6 non-zero cells in the matrix, i.e. 2 in the first and at most 4 in the 2nd. Thus, the above approach allows us to ignore almost 70% of the cells.

### 5 ALL_SUM UNDER ATTRIBUTE-LEVEL MODEL

Due to the significant differences between the tuple-level and the attribute-level models it is not trivial to adapt our yet proposed algorithms for the attribute-level model.
In this section, we propose our solution for computing ALL_SUM results under the attribute-level model.

5.1 Recursive Approach
We propose a recursive approach for computing ALL_SUM under the attribute-level model. This approach is the basis for a dynamic programming algorithm that we describe next. We assume that all tuples have the same number of possible aggr values, say \( m \). This assumption can be easily relaxed as we do in Appendix B. We also assume that, in each tuple \( t \), the sum of the probabilities of possible aggr values is 1, i.e. \( p_{1,k} + p_{2,k} + \ldots + p_{m,k} = 1 \). In other words, we assume that there is no null value. However, this assumption can be relaxed as in Appendix A.

5.1.1 Recursion Base
Let us consider \( DB^1 \), i.e. a database that only involves \( t_1 \). Let \( v_{1,1}, v_{1,2}, \ldots, v_{1,m} \) be the possible values of the aggr attribute of \( t_1 \), and \( p_{1,1}, p_{1,2}, \ldots, p_{1,m} \) their probabilities. We construct \( DB^1 \) by adding \( t_1 \) to \( DB^0 \). The worlds of \( DB^0 \) are constructed by adding to each \( w \in W^{n-1} \), each possible value of \( t_1 \). Let \( W^n \subset W^{n-1} \) be the set of worlds which are constructed by adding the possible value \( v_{1,k} \) of \( t_1 \) to the worlds of \( W^{n-1} \). Indeed, for each world \( w \in W^{n-1} \), there is a corresponding world \( w' \in W^n \) such that \( w' = w + \{t_1\} \) where the possible aggr value of \( t_1 \) is equal to \( v_{1,k} \). This implies that for each possible \( sum^i \) with probability \( p \) in \( W^{n-1} \), there is a possible \( sum = i + v_{1,k} \) with probability \( p \times p_{1,k} \) in \( W^n \). Recall that \( ps(t_i, n-1) \) is the aggregate probability of the \( DB^1 \) worlds in which \( sum = i \). Then we have:

\[
prob(sum=i) = ps(i-v_{1,k}, n-1) \times p_{1,k}
\]

Let \( ps(i, n) \) be the probability of \( sum^i \) in \( DB^0 \). Since we have \( W^n = W^1 \cup W^2 \cup \ldots \cup W^m \), the probability of \( sum^i \) in \( W^n \) is equal to the sum of the probabilities of \( sum^i \) in \( W^1, W^2, \ldots \) and \( W^m \). Thus, using Equation 6 and the recursion base of Equation 5, the probability of \( sum^i \) in \( DB^0 \), i.e. \( ps(i, n) \), can be stated as follows:

\[
ps(i, n) = \begin{cases} 
\sum_{k=1}^{m} ps(i-v_{1,k}, n-1) \times p_{1,k} & \text{if } n > 1 \\
p_{1,k} & \text{if } n = 1 \text{ and } \exists k \text{ such that } v_{1,k} = i \\
0 & \text{otherwise}
\end{cases}
\]

5.2 Dynamic Programming Algorithm for Attribute-level Model
Now, we describe a dynamic programming algorithm, called \( DP_{PSUM} \), for computing ALL_SUM under the attribute-level model. Here, similar to the basic version of \( DP_{PSUM} \) algorithm, we assume integer values. However, in a way similar to that of \( DP_{PSUM} \), this assumption can be relaxed. Let \( PS \) be a 2D matrix with \( \text{MaxSum} + 1 \) rows and \( n \) columns, where \( n \) is the number of tuples and \( \text{MaxSum} \) is the maximum possible sum, i.e. the sum of the greatest values of aggr attribute in the tuples. At the end of \( DP_{PSUM} \) execution, \( PS[i,j] \) contains the probability of \( sum^i \) in a database involving tuples \( t_1, \ldots, t_j \).

\( DP_{PSUM} \) works in two steps. In the first step, it initializes the first column of the matrix, by using the base of the recursive definition, as follows. For each possible aggr value of tuple \( t_1 \), e.g. \( v_{1,k} \), it sets the corresponding entry equal to the probability of the possible value, i.e. it sets \( P[v_{1,k}, 1] = p_{1,k} \) for \( 1 \leq k \leq m \).

In the second step, \( DP_{PSUM} \) sets the entry values of each column \( j \) (for \( 2 \leq j \leq n \)) by using the recursion step of the recursive definition, and based on the values yet set in precedent column. Formally, for each column \( j \) and row \( i \) it sets \( PS[i, j] = \sum (PS[i-v_{1,k}, j-1] \times p_{1,k}) \) for \( 2 \leq k \leq m \) such that \( i \geq v_{1,k} \).

Let us now analyze the complexity of the algorithm. Let \( \text{avg} = \frac{\text{MaxSum}}{n} \), i.e. the average of the aggregate attribute values. The space complexity of \( DP_{PSUM} \) is exactly the same as that of \( DP_{PSUM} \), i.e. \( O(n^2 \times \text{avg}) \). The time complexity of \( DP_{PSUM} \) is \( O(\text{MaxSum} \times n \times \text{avg}) \). In other words its time complexity is \( O(n^2 \times \text{avg}) \).

Let us now illustrate the \( DB_{PSUM} \) algorithm using...
an example.

**Example 4.** Consider the database in Figure 8.a which is under attribute-level model. The execution of the DP_PSUM2 algorithm is shown in Figure 8.b. The first column of the matrix is filled using the probabilities of the possible agrgr values of \( t_1 \). Thus, we set 0.3 and 0.7 for sum values 1 and 2 respectively. The other columns are filled by using our recursive definition. After the execution of the algorithm, the 3rd column shows the probability of all sum results for our example database.

6 Extensions

In this section, we extend our algorithm to deal with the x-relation model, and correlated databases with mutual exclusions. We also show how our ALL_SUM algorithms can be used for computing the results of COUNT aggregate queries.

6.1 ALL_SUM in X-Relation Model

In the X-Relation model [1], a probabilistic table is composed of a set of independent x-tuples, such that each x-tuple consists of some mutually exclusive tuples, called alternatives. Each alternative is associated with a probability. If every x-tuple consists of only one alternative, then the x-relation is equivalent to our tuple-level model. In this case, ALL_SUM query processing can be done using the algorithms developed for tuple-level model.

Let us deal with the problem of evaluating ALL_SUM queries for the case of multiple alternative x-tuples. This problem can be reduced to a problem in the attribute-level model as follows. Let \( Q \) be the ALL_SUM query, and \( \alpha \) be the agrgr attribute. Let \( D \) be the given database in the x-relation model. We convert \( D \) to a database \( D' \) in the attribute-level model such that the result of the query \( Q \) in \( D' \) be the same as that of \( D \). The database \( D' \) is constructed as follows. For each x-tuple \( x \) in \( D \), we create a tuple \( t' \) in \( D' \) with an attribute \( \alpha \). Let \( T \) be the set of x's alternative tuples. Let \( T' \subseteq T \) be the set of tuples in \( T \) that satisfy the \( Q \)'s predicates. The values of the attribute \( \alpha \) in \( t' \) will be the distinct values of this attribute in the tuples involved in \( T' \), and probability of each value is computed in a similar way as a projection on \( \alpha \). In other words, if a value appears in only one alternative of \( x \), then its probability is equal to the probability of the alternative. Otherwise, i.e. when a value appears in multiple alternatives, its probability is equal to the probability that at least one of the alternatives exists.

Now, the database \( D' \) is under the attribute-level model, and we can apply our ALL_SUM algorithms to evaluate ALL_SUM queries over it.

6.2 ALL_SUM over Correlated Databases

In previous sections, we assumed that the tuples of the database are independent. Here, we assume mutual exclusion correlations, and show how to execute over ALL_SUM algorithms over databases that contain such correlation. Two tuples \( t_1 \) and \( t_2 \) are mutually exclusive, iff they cannot appear together in any instance of the database (i.e. possible world). But, there may be instances in which none of them appear. As an example of mutual exclusive tuples we can mention the tuples that are produced by two sensors that monitor the same object at the same time. In this example, at most one of the produced tuples can be correct, so they are mutually exclusive.

It has been shown that the tuples of a correlated database with mutual exclusions can be grouped to a set of blocks such that there is no dependency between any two tuples that belong to two different blocks, and there are closure dependencies between any two tuples of each block [11]. These blocks are in fact x-tuples with multiple alternatives. Thus, to evaluate ALL_SUM queries on them, it is sufficient to convert the given database to a database \( D' \) in the attribute-level model as shown in Section 6.1, and then apply an ALL-SUM algorithm that works on the attribute-level model.

6.3 Evaluating ALL_COUNT Queries Using ALL_SUM Algorithms

We now show how we can evaluate ALL_COUNT queries, i.e. all possible counts and their probabilities, using the algorithms that we proposed for ALL_SUM. Under the attribute-level model, all tuples are assumed to exist, thus the result of a count query is always equal to the number of tuples that satisfy the query. However, under the tuple-level model, the problem of evaluating ALL_COUNT is harder because there may be \( (n+1) \) possible count results (i.e. from 0 to \( n \)) with different probabilities, where \( n \) is the number of uncertain tuples. This is why we deal with ALL_COUNT only under the tuple-level model.

The problem of ALL_COUNT can be reduced to that of ALL_SUM in polynomial time as follows. Let \( D \) be the database on which we want to execute ALL_COUNT. We generate a new database \( D' \) as follows. For each tuple \( t \in D \) we generate a tuple \( t' \) in \( D' \) such that \( t' \) involves only one attribute, e.g. \( B \), with two possible values: \( v_1=1 \) and \( v_2=0 \). We set \( p(v_1) \) equal to the membership probability of \( t \). We set \( p(v_2)=1-p(v_1) \). Now, if we apply one of our ALL_SUM algorithms over \( B \) as agrgr attribute in \( D' \), the result is equivalent to applying an ALL_COUNT algorithm over the agrgr attribute in \( D \). This is proven by the following theorem.

**Theorem 2.** If the database \( D \) is under the tuple-level model, then the result of ALL_SUM over the attribute \( B \) in database \( D' \) is equivalent to the result of ALL_COUNT over the aggregate attribute of the database \( D \).

**Proof.** If the database \( D \) is under the tuple-level model, its membership probability in \( D \) is equal to the probability of value \( v_1=1 \) in attribute \( B \) of \( D' \). Thus, the contribution of a tuple \( t \) to COUNT in the database \( D \) is equal to the contribution of its corresponding tuple \( t' \) to SUM in the database \( D' \). In other words, the results of ALL_SUM over \( D' \) is equivalent to the results of ALL_COUNT over \( D \). □

7 Experimental Validation

To validate our algorithms and investigate the impact of different parameters, we conducted a thorough experimental evaluation. In Section 7.1, we describe our ex-
7.1 Experimental Setup
We implemented our DP_PSUM and Q_PSUM algorithms in Java, and we validated them over both real-world and synthetic databases.

As real-world database, like some previous works, e.g. [18][21], we used the data collected in the International Ice Patrol (IIP) Iceberg Sightings Database (http://nsidc.org/data/g00807.html) whose data is about the iceberg evolution sightings in North America. The database contains attributes such as iceberg, number, sighting date, shape of the iceberg, number of days drifted, etc. There is an attribute that shows the confidence level about the source of sighting. In the dataset that we used, i.e. that of 2008, there are 6 confidence levels: R/V (radar and visual), VIS (visual only), RAD (radar only), SAT-LOW (low orbit satellite), SAT-MED (medium orbit satellite) and SAT-HIGH (high orbit satellite). Like in [18] and [21], we quantified these confidence levels by 0.8, 0.7, 0.6, 0.5, 0.4 and 0.3 respectively. As aggr attribute, we used the number of drifted days that contains real numbers with one digit of precision in the interval of [0…365].

As synthetic data, we generated databases under the attribute-level model that is more complete than the tuple-level model. We generated two types of databases, Uniform and Gaussian, in which the values of attributes in tuples are generated using a random generator with the uniform and Gaussian distributions, respectively. The default database is Uniform, and the mean (average) of the generated values is 10. Unless otherwise specified, for the Gaussian database the variance is half of the mean. The default number of attribute values in each tuple of our attribute-value model is 2.

In the experiments, we evaluated the performance of our DP_PSUM and Q_PSUM algorithms. We also compared their performance with that of the naïve algorithm that enumerates the possible worlds, computes the sum in each world, and returns the possible sum values and the aggregated probability of the worlds where they appear as the result of sum. To manage the possible sum values, we used a B-tree structure.

For the three algorithms, we measured their response time. We conducted our experiments on a machine with a 2.66 GHz Intel Core 2 Duo processor and 2GB
memory.

7.2 Performance Results
In this section, we report the results of our experiments.

Effect of the number of uncertain tuples. Using the synthetic data, Figure 9 shows the response time of the three algorithms vs. the number of uncertain tuples, i.e. \( n \), and the other experimental parameters set as described in Section 7.1. The best algorithm is DP_PSUM, and the worst is the Naïve algorithm. For \( n \geq 30 \), the response time of the Naïve algorithm is too long, such that we had to halt it. This is why we do not show its response time for \( n \geq 30 \). The response time of DP_PSUM is at least four times lower than that of Q_PSUM (notice that the figure is in logarithmic scale).

Over the IIP database, Figure 10 shows the response time of the three algorithms, with different samples of the IIP database. In each sample, we picked a set of \( n \) tuples, from the first to the \( n \)th tuple of the database. Overall, the results are qualitatively in accordance with those over synthetic data. However, the response time over the real database is higher than that of the synthetic database. The main reason is that the precision of the real data is 1, i.e. there is one digit after the decimal point. This increases the execution time of our algorithms significantly. For example, in the case of DP_PSUM, the execution time can increase up to ten times, and this confirms the complexity analysis of real value processing in Section 4.3.

Effect of data distribution. Figure 11 shows the response time of our algorithms over the Uniform and Gaussian databases. The response time of DP_PSUM over uniform distribution increases, but not significantly, i.e. less than 30%. The higher performance of DP_PSUM over the uniform distribution is due to the higher number of zero points, which can be skipped (see Table 1), thus less computation is needed. Another reason is the value of MaxSum, i.e. the maximum possible sum value, which is lower for the uniform dataset as shown in Table 1.

The impact of the distribution on Q_PSUM is much more significant, i.e. about two times more than on the DP_PSUM. The reason is that the distribution of the attribute values affects the number of possible sum results, i.e. with the Gaussian distribution the number of possible sum values is much more than that of the uniform distribution.

Table 1. The value of MaxSum and the percentage of zero points during the execution of DP_PSUM algorithm on uniform and Gaussian datasets.

<table>

<td>2577</td>
<td>3123</td>
</tr>
<tr>
<td>Rate of zero value cells</td>
<td>0.73%</td>
<td>0.63%</td>
</tr>
</tbody>
</table>

Effect of average. We performed tests to study the effect of the average of aggregate values in the database, i.e. \( \text{avg} \), on performance. Using the synthetic data, Figure 12 shows the response time of our DP_PSUM and Q_PSUM algorithms with \( \text{avg} \) increasing up to 50, and the other experimental parameters set as described in Section 7.1. The average of aggregate values has a linear impact on DP_PSUM and this is in accordance with the complexity analysis done in Section 4. What was not expected is that the impact of \( \text{avg} \) on the performance of Q_PSUM is significant, although \( \text{avg} \) is not a direct parameter in the complexity of Q_PSUM (see Section 3.2). The explanation is that the time complexity of Q_PSUM depends on the number of possible SUM results, and when we increase \( \text{avg} \) (i.e. mean) of the aggregate values, their range become larger, thus the total number of possible sum values increases.

Effect of the number of attribute values per tuple. We tested the effect of the number of attribute values in each tuple under the attribute-level model, i.e. \( m \), on performance. Figure 13 shows the response time of our algorithms with increasing \( m \) up to 10, and other parameters set as in Table 1. This number has a slight impact on DP_PSUM, but a more considerable impact on Q_PSUM.

Effect of precision. We studied the effect of the precision of real numbers, i.e. the number of digits after decimal point, on the performance of the DP_PSUM algorithm. Using the synthetic data, Figure 14 shows the response time with increasing the precision of the aggr values. As shown, the precision has a significant impact on the response time of DP_PSUM, i.e. about ten times for each precision digit. This is in accordance with our theoretical analysis done in Section 4, and shows that our algorithm is not appropriate for the applications in which the aggr values are real numbers with many digits after the decimal point.

8 RELATED WORK
In the recent years, we have been witnessing much interest in uncertain data management in many application areas such as data cleaning [3], sensor networks [12][21], information extraction [19], etc. Much research effort has been devoted to several aspects of uncertain data management, including data modeling [4][6][10][16][17][29], skyline queries [5][26], top-k queries [9][13][18][30], nearest neighbor search [31][33][35], spatial queries [34], XML documents [1][24][25], etc.

There has been some work dealing with aggregate query processing over uncertain data. Some of them were devoted to developing efficient algorithms for returning the expected value of aggregate values, e.g. [7][20]. For example in [20], the authors study the problem of computing aggregate operators on probabilistic data in an I/O efficient manner. With the expected value semantics, the evaluation of SUM queries is not very challenging. In [10], Dalvi and Suciu consider both expected value and ALL_SUM, but they only propose an efficient approach for computing the expected value.

Approximate algorithms have been proposed for probabilistic aggregate queries, e.g. [8] and [28]. The Central Limit theorem [27] can be used to approximately estimate the distribution of sums for sufficiently large numbers of probabilistic values. However, in the current
paper, our objective is to return exact probability values, not approximations.

In [23] and [32], aggregate queries over uncertain data streams have been studied. For example, Kanagal et al. [23] deal with continuous queries over correlated uncertain data streams. They assume correlated data which are Markovian and structured in nature. Their probabilistic model and the assumptions, and as a result the possible algorithms, are very different from ours. For example in their model, they propose algorithms that deal with MIN/MAX queries in a time complexity that does not depend on the number of tuples. However, in our model it is not possible to develop algorithms with such a complexity.

The work in [11] studies the problem of HAVING aggregate queries with predicates. The addressed problem is related to the #KNAPSACK problem which is NP-hard. The difference between HAVING-SUM queries in [11] and our ALL_SUM queries is that in ALL_SUM we return all possible SUM values and their probabilities, but in HAVING-SUM the goal is to check a condition on an aggregate function, e.g. is it possible to have SUM equal to a given value.

Overall, for the problem that we considered in this paper, i.e. returning the exact results of ALL_SUM queries, there is no efficient solution in the related work. In this paper, we proposed pseudo polynomial algorithms that allow us to efficiently evaluate ALL_SUM queries in many practical cases, e.g. where the aggregate attribute values are small integers, or real numbers with limited precisions.

9 Conclusion

SUM aggr queries are critical for many applications that need to deal with uncertain data. In this paper, we addressed the problem of evaluating ALL_SUM queries. After proposing a new recursive approach, we developed an algorithm, called Q_PSUM, which is polynomial in the number of SUM results. Then, we proposed a more efficient algorithm, called DP_PSUM, which is very efficient in the cases where the aggr attribute values are small integers or real numbers with small precision. We validated our algorithms through implementation and experimentation over synthetic and real-world data sets. The results show the effectiveness of our solution. The performance of DP_PSUM is usually better than that of Q_PSUM. Only over special databases with small numbers of possible sum results and very large aggr value average, Q_PSUM is better than DP_PSUM.

References

Appendix A: Dealing with Null Values

In classical (non probabilistic) databases, when processing SUM queries, the null (unknown) values are usually replaced by zero. Under the tuple level model, the null value has the same meaning as in classical databases. Thus, we simply replace the null values by zero without changing their probabilities.

Under the attribute level model, the null values are taken into account as follows. Let \( t_i \) be a tuple under this model, \( v_{i,1}, v_{i,2}, \ldots, v_{i,m} \) the possible values for the aggr attribute of \( t_i \) and \( p_{i,1}, p_{i,2}, \ldots, p_{i,m} \) their probabilities. Let \( p \) be the sum of the probability of possible values in \( t_i \), i.e. \( p = p_{i,1} + p_{i,2} + \ldots + p_{i,m} \). If \( p < 1 \), then there is the possibility of null value (i.e. unknown value) in tuple \( t_i \), and the probability of the null value is \( (1-p) \). We replace null values by zero as follows. If the zero value is among the possible values of \( t_i \), i.e. there is some \( v_{i,j} = 0 \) for \( 1 \leq j \leq m \), then we add \( (1-p) \) to its probability, i.e. we set \( p_{i,j} = p_{i,j} + 1 - p \). Otherwise, we add the zero value to the possible values of \( t_i \) and set its probability equal to \((1-p)\).

Appendix B: Dealing with Tuples with Different Possible Aggr Values

Under the attribute level model, in our recursive ap-
proach for computing SUM we assumed that all tuples have the same number of possible aggr values. However, there may be cases where the number of possible aggr values in tuples is not the same. We deal with those cases as follows. Let $t$ be the tuple with maximum number of possible aggr values. We set $m$ to be equal to the number of possible values in $t$. For each other tuple $t'$, let $m'$ be the number of possible aggr values. If $m' < m$, we add $(m - m')$ new distinct values to the set of possible values of $t'$, and we set the probability of new values to zero. Obviously, the new added values have no impact on the results of ALL_SUM queries because their probability is zero. Thus, by this method, we make the number of possible aggr values in all tuples equal to $m$, without impacting the results of ALL_SUM queries.

Appendix C: Pseudocode of AL_SUM algorithms
Figure 15 and Figure 16 show the pseudocode of the Q_PSUM and DP_PSUM algorithms.
