\textbf{Abstract.} Sequential pattern mining is an approach to extract correlations among temporal data. Many different methods were proposed to either enumerate sequences of set valued data (i.e., itemsets) or sequences containing multidimensional items. However, in many real-world scenarios, data sequences are described as events of both multi-dimensional and set valued informations. These rich heterogeneous descriptions cannot be exploited by traditional approaches. For example, in healthcare domain, hospitalizations are defined as sequences of multi-dimensional attributes (e.g. Hospital or Diagnosis) associated with sets of medical procedures (e.g. \{Radiography, Appendectomy\}). In this paper we propose a new approach called MMISP (\textit{Mining Multi-dimensional-Itemset Sequential Patterns}) to extract patterns from sequences including both multi-dimensional and set valued data. The novelties of the proposal lies in: (i) the way in which the data can be efficiently compressed; (ii) the ability to reuse a state-of-the-art sequential pattern mining algorithm and (iii) the extraction of new kind of patterns. We introduce as a case-study, experiments on real data aggregated from a regional healthcare system and we point out the usefulness of the extracted patterns. Additional experiments on synthetic data highlights the efficiency and scalability of our approach.

\section{Introduction}

Data warehouses are constituting a large source of informations that are used and exploited to extract useful knowledge for expert analysis and decision makers \cite{[3]}. In temporal data warehouses, every bit of information is associated with a timeline describing a total order over events. This particular ordering introduces more complexity to the extraction process and more precisely to mining
processes that enumerate patterns that encompass interesting transient events. Many efficient approaches were developed to mine these patterns (i.e., sequential patterns) like PrefixSpan [5], SPADE [12], SPAM [1], PSP [4], DISC [2], PAID [10], FAST [8]. However, all these techniques and algorithms, without any exception, focus solely on sequences of set valued data (i.e., itemsets) and contrast with real-world data that have multiple dimensions. To overcome this problem, Pinto et al. [6] introduced the notion of multi-dimensionality in sequences and proposed an efficient algorithm. Later works, like Zhang et al. [13] or Yu et al. [11] extended the initial Pinto’s approach for different scenarios and use-cases. While in set valued approaches the events are represented by itemsets, in multi-dimensional temporal databases the events are defined over a fixed schema in which all the attributes are mandatory in the extracted patterns. Furthermore, and this is particularly true in the data warehouse environment, background knowledge is usually available and can be represented as a hierarchy over the values of the attributes. Following this logic, Plantevit et al. introduced M3SP [7], an efficient algorithm that is able to incorporate different dimensions and their ordering (organization) in the sequential pattern mining process. The benefit of this approach is to extract patterns with the most appropriate level of granularity. Still, this idyllic representation of uniform data is very uncommon in real-world applications where heterogeneity is usually elevated to a foundational concept. In this study, we focus on extracting knowledge from medical data warehouse representing information about patients in different hospitals. The successive hospitalizations of a patient can be expressed as a sequence of multi-dimensional attributes associated with a set of medical procedures. Our goal is to be able to extract patterns that express patients stays along with combinations of procedures over time. This type of pattern is very useful to healthcare professionals to better understand the global behavior of patients over time. Unfortunately this full richness and complexity of the data cannot be exploited by any of the traditional sequential pattern mining techniques. In this paper, we propose a new approach to extract patterns from sequences which include multi-dimensional and set valued data at the same time. In addition, the proposed approach incorporates background knowledge in the form of hierarchies over attributes.

The remainder of this paper is organized as follows, Section 2 introduces the problem statement as well as a running example. The method for extracting multi-dimensional-itemset frequent patterns is described in Section 3. Section 4 presents experimental results from both quantitative and qualitative point of views and Section 5 concludes the paper.

2 Problem Statement

In this section we list some preliminary definitions needed to formalize and present our problem. First of all, we introduce a motivating example from a real data set related to the PMSI (Program of medical information systems). This French nationwide information system describes hospital activities from
both economical and medical points of view. In this system, each hospitalization is related to the recording of administrative, demographical and medical data.

Table 1. An example of a database of patient trajectories

Let $S_{DB}$ be a database of multi-dimensional-itemset data sequences. Table 1 illustrates such a database.

**Definition 1.** (Dimensions and specialization down($d$)) A dimension $(D, \leq)$ is a partially ordered set. For a given $d$ in $D$, down($d$) (resp. up($d$)) denotes the set of all specializations $\{x \in D | x \leq d\}$ (resp. generalizations $\{x \in D | d \leq x\}$) of $d$.

**Example 1.** Figure 1 shows two hierarchical taxonomies characterizing both the hospital and diagnosis dimensions. For hospital dimension, $UH_{Paris}$ is a direct descendant of $UH$.

![Fig. 1. Hospital and diagnoses taxonomies](image)

By taking into account taxonomies, we define a multi-dimensional component as follows:

**Definition 2.** (Multi-dimensional component) Given a dimension $(D, \leq)$, a multi-dimensional component over $D$, denoted $(mdc, \leq_{mdc})$, is a tuple $(d_1, \ldots, d_m)$ where $d_i \in D$, $i = 1, \ldots, m$. For two given multidimensional components $mdc = (d_1, \ldots, d_m)$ and $mdc' = (d'_1, \ldots, d'_m)$, $mdc' \leq_{mdc} mdc$ denotes that $mdc'$ is more specific than $mdc$, if for every $i = 1, \ldots, m$, $d'_i \in \text{down}(d_i)$.

**Example 2.** Let $(UH_{Paris}, \text{Lung Cancer})$ and $(UH, \text{Cancer})$ be two multidimensional components. $(UH_{Paris}, \text{Lung Cancer}) \leq_{mdc} (UH, \text{Cancer})$ because $UH_{Paris} \in \text{down}(UH)$ and Lung Cancer $\in \text{down}(\text{Cancer})$. 
**Definition 3.** (Event) An event \( e = ((d_1, ..., d_m), \{p_1, ..., p_n\}) \) is a pair including a multidimensional component and an associated itemset. Given two events \( e = ((d_1, ..., d_m), \{p_1, ..., p_n\}) \) and \( e' = ((d'_1, ..., d'_m), \{p'_1, ..., p'_n\}) \), \( e \) is included in \( e' \), denoted by \( e \subseteq e' \), if and only if \( (d_1, ..., d_m) \leq_{mdc} (d'_1, ..., d'_m) \) and \( \{p_1, ..., p_n\} \subseteq \{p'_1, ..., p'_n\} \).

**Example 3.** \( e = ((UH, T_{disease}), \{p_1, p_2, p_3\}) \) is an event, where \((UH, T_{disease})\) is a multidimensional component with two dimensions representing hospital and diagnosis. \( \{p_1, p_2, p_3\} \) denotes the set of medical procedures. An event \( e' = ((UH_{Paris}, C_1), \{p_1, p_2\}) \) is included in \( e \), \( e' \subseteq e \), because \((UH_{Paris}, C_1) \leq_{mdc} (UH, T_{disease}) \) and \( \{p_1, p_2\} \subseteq \{p_1, p_2, p_3\} \).

A multi-dimensional-itemset data sequence is composed of events.

**Definition 4.** (Multi-dimensional-itemset Sequence) A multi-dimensional-itemset sequence \( s = \langle e_1, e_2, ..., e_l \rangle \) is an ordered list of events \( e_i \). Given two multidimensional-itemset sequences \( s = \langle e_1, e_2, ..., e_l \rangle \) and \( s' = \langle e'_1, e'_2, ..., e'_{l'} \rangle \), \( s \) is included in \( s' \), denoted by \( s \subseteq s' \), if there exist indices \( 1 \leq i_1 < i_2 < ... < i_1 \leq l' \) such that \( e_j \subseteq e'_j \) for all \( j = 1 \ldots l \) and \( l \leq l' \).

**Example 4.** The sequence \( s = \langle ((UH_{Paris}, Cancer), \{p_1, p_2\}), ((GH_{Lyon}, R_1), \{p_2\}) \rangle \) is a sequence of two events. It expresses the fact that a patient was admitted to the University Hospital of Paris \( UH_{Paris} \) for a cancer disease \( Cancer \) and underwent procedures \( p_1 \) and \( p_2 \), then he went to the General Hospital of Lyon \( GH_{Lyon} \) for pneumonitis \( R_1 \) and underwent procedure \( p_2 \). A sequence \( s' = \langle ((UH_{Paris}, C_1), \{p_1\}) \rangle \) is included in \( s \), \( s' \subseteq s \), because \((UH_{Paris}, C_1) \leq_{mdc} (UH_{Paris}, Cancer), \{p_1, p_2\}) \).

**Definition 5.** (Patient Trajectory) A patient trajectory is defined as a multi-dimensional-itemset sequence.

**Example 5.** In Table 1, the sequence \( s = \langle ((UH_{Paris}, C_1), \{p_1, p_2\}), ((UH_{Paris}, C_1), \{p_1\}), ((GH_{Lyon}, R_1), \{p_2\}) \rangle \) represents the trajectory for the patient \( P_1 \).

Let \( \text{supp}(s) \) be the number of sequences that includes \( s \) in \( S_{DB} \). Furthermore \( \sigma \) be a minimum support threshold specified by the end-user.

**Definition 6.** (Most Specific Frequent Sequence) Let \( s \) be multi-dimensional-itemset sequences, we can say that, \( s \) is the most specific frequent sequences in \( S_{DB} \), if and only if: \( \text{supp}(s) \geq \sigma \) and \( \nexists s' \in S_{DB} \), where \( \text{supp}(s) = \text{supp}(s') \) and \( s' \subseteq s \).

**Problem 1.** The problem of mining multi-dimensional-itemset sequences is to extract the set of all most specific frequent sequences in \( S_{DB} \) such as \( \text{supp}(s) \geq \sigma \). By using the taxonomies we can extract more or less general or specific patterns and overcome problems of excessive granularity and low support.

**Example 6.** Let \( \sigma = 0.75 \) (i.e. a sequence is frequent if it appears at least three times in \( S_{DB} \)). The sequence \( s_1 = \langle (UH_{Paris}, C_1), \{p_1, p_2\}, ((GH_{Lyon}, R_1), \{p_2\}) \rangle \) is frequent. \( s_2 = \langle (UH, Cancer), \{p_1, p_2\}, ((GH, Respiratory), \{p_2\}) \rangle \) is also frequent. Nevertheless, \( s_2 \) is not kept since it is too general compared to \( s_1 \).
3 Mining Multi-dimensional-Itemset Sequential Patterns

In this section, we present the MMISP (Mining Multi-dimensional-Itemset Sequential Patterns) algorithm for extracting multi-dimensional-itemset sequential patterns with different levels of granularity over each dimension. MMISP follows a bottom-up approach by first focusing on extracting *mdc* that can exist at different levels of granularity, then it considers the itemset part of the events and compute the support of every item is $S_{DB}$. After these two steps, frequent multi-dimensional components and frequent items are combined to generate events. In the final step, the frequent events are mapped to a new representation and a standard sequential mining algorithm is applied to enumerate multi-dimensional itemset sequential patterns.

In the next subsections, we provide the details of each step of our work and discuss the different challenges.

3.1 Generating Multi-dimensional Components

MMISP starts by processing the multi-dimensional components of the sequences. Basically it considers three types of dimensions: a temporal dimension $D_t$, a set of analysis dimensions $D_A$ and a set of reference dimensions $D_R$. MMISP splits $S_{DB}$ into blocks according to reference dimension $D_R$. Then, MMISP sorts each block according to the temporal dimension $D_t$. The tuples of multi-dimensional component appearing in an event are defined w.r.t. analysis dimensions $D_A$. The support of the multi-dimensional component is computed according to dimensions of $D_R$. It is the ratio of the number of blocks supporting the multi-dimensional component over the total number of blocks. This a classic way of partitioning the database and was introduced in [7].

Example 7. In our example, $H$ (hospitals) and $D$ (diseases) are the analysis dimensions, $Date$ is the temporal dimension, and $P$ (patients) is the reference dimension. By using $P$ (patients) to split the dataset, we obtain four blocks defined by $Patient_1$, $Patient_2$, $Patient_3$ and $Patient_4$ as shown in Figure 2.

</tr>
</tbody>
</table>

Block: *Patient_4*

Fig. 2. Block partition of the database according to $D_R=\{Patient\}$
Following this partitioning step, MMISP generates all the frequent multi-dimensional components. Firstly, we generate the most general multi-dimensional component, that is \((T_1, \ldots, T_m)\). In our running example, we have two dimensions (hospital and disease), so the most general multi-dimensional component is \((T_{hospital}, T_{disease})\). Then, our approach generates all multi-dimensional components of the form \((T_1, \ldots T_{i-1}, d_i, T_{i+1}, \ldots, T_m)\) where \(d_i \in \text{down}(T_i)\). We take only the frequent multi-dimensional component which has support greater than \(\sigma\). In our running example and for \(\sigma = 75\% (3 \text{ blocks from } 4)\), we have four new frequent multidimensional components: \((UH, T_{disease})\), \((GH, T_{disease})\), \((T_{hospital}, \text{Respiratory})\) and \((T_{hospital}, \text{Cancer})\).

We continue the recursive generation of the new multidimensional components by using each previously generated frequent multidimensional component \((a)\). This is done with a pivot method that identifies an integer \(z\) which is the position of the last dimension in \(a\) and is not top \(T\). For example if \(a = (UH, T_{Disease})\), \(z\) is the first dimension (hospital) because the value for the hospital dimension (UH) and the second dimension (disease) has the value \(T_{disease}\).

For each dimension \(d_k\) in \(a\), where \(k \in [z, m]\), we replace \(d_k\) with one of its specialization from the set \(\text{down}(d_k)\). For example, if \(a = (UH, T_{Disease})\), we have \(z = 1\) and we can generate four new \(mdc\): \{\((UH_{Paris}, T_{Disease}), (UH_{Nancy}, T_{Disease}), (UH, \text{Respiratory}), (UH, \text{Cancer})\)\}. The first and the second multidimensional components are generated by replacing \(UH\) by \(\text{down}(UH) = \{UH_{Paris}, UH_{Nancy}\}\), the third and the forth multidimensional components are generated by replacing \(T_{Disease}\) by \(\text{down}(T_{Disease}) = \{\text{Respiratory}, \text{Cancer}\}\).

We select only the frequent multidimensional components. For our previously example with \(\sigma = 75\%\), \{\((UH_{Paris}, T_{Disease}), (UH, \text{Cancer})\)\} are the new frequent multidimensional components generated by \((UH, T_{Disease})\).

Finally, from all frequent multi-dimensional components generated, we select only the most specific multi-dimensional component.

**Definition 7.** (Most Specific Multi-dimensional Component) Let \(a\) be multi-dimensional component, we can say that, \(a\) is the most specific multi-dimensional component, if and only if \(\exists a\) multi-dimensional component, where \(\text{supp}(a) = \text{supp}(a')\) and \(a' \leq_{mdc} a\).

<table>
<thead>
<tr>
<th>Frequent multi-dimensional component</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td>((GH_{Lyon}, R_1))</td>
</tr>
</tbody>
</table>

**Table 2.** The most specific frequent multi-dimensional components

**Example 8.** Figure 3 illustrates the mechanism work of generation all frequent multi-dimensional components on our running example with \(\sigma = 0.75\). We can notice that the most specific components are \((UH_{Paris}, C_1)\) and \((GH_{Lyon}, R_1)\).
3.2 Generating Frequent Itemset

In this step, MMISP focuses on the itemset part of the sequences. Basically, this step aims at extracting the set of all items that are frequent in a sequence of length 1. Let us remind that usually, in level-wise approaches, either itemset-extension or sequence-extension can be considered. For example, if we have a sequence \( s_1 = \{1, 2, 3\} \), then \( s_2 = \{1, 2, 3, 4\} \) is a sequence-extended sequence of \( s_1 \) and \( s_3 = \{1, 2, 3, 4\} \) is an itemset-extended sequence of \( s_1 \). In our context focusing on sequence of length 1 we will only consider itemset-extension. Such an operation can be easily done by using any standard sequential pattern algorithm.

\[
\begin{array}{c|c}
\text{Patients} & \text{Sequences of procedures} \\
\hline
P_1 & \{(p_1, p_2)\} \\
P_2 & \{(p_1)\} \\
P_3 & \{(p_2)\} \\
\hline
\end{array}
\]

\[
\begin{array}{c|c}
\text{Frequent Itemset Candidates} & \\
\hline
\{p_1\} \\
\{p_2\} \\
\end{array}
\]

Fig. 4. The frequent itemset generated

\textbf{Example 9.} Figure 4 shows the sequence of medical procedures for patients and the frequent itemset candidates for \( \sigma = 0.75 \).

3.3 Generating Frequent Events

Generating frequent events is achieved by combining frequent multi-dimensional components with frequent itemsets. This task is achieved by building a prefix tree such that the first level in this tree is composed of the frequent multi-dimensional components and the second level is composed the frequent itemsets. More precisely, each branch in the tree represents an event. Then a scan is performed
over the database to prune irrelevant events from the tree. For example, Figure 5 illustrates the tree before and after pruning infrequent events for $\sigma = 0.75$.

Combination tree before pruning
Combination tree after pruning

Fig. 5. An example of the tree for generating frequent events before and after the pruning

### 3.4 Extracting Frequent Multi-dimensional Itemset Patterns

Frequent sequences can then be mined by using any standard sequential pattern mining algorithm. As these algorithms require that the dataset to be mined is composed of pairs in the form $(id, seq)$, where $id$ is a sequence identifier and $seq$ is a sequence of itemsets, we transform the initial dataset as follows:

- Each branch in the combination tree after pruning is assigned a unique id which will be used during the mining operation. This is illustrated in Table 3.
- Each block (patient) is assigned a unique id of the form $P_i$.
- Every block $b$ is transformed into a pair $(P_i, S(p_i))$, where $S(P_i)$ is built according to the date and the content of the blocks. The final result is reported in Table 4.

A standard sequence mining algorithm can be applied on the transformed database.

<table>
<thead>
<tr>
<th>Event-id</th>
<th>Frequent Event</th>

<tr>
<td>3</td>
<td>$(e_1, e_2) {e_4}$</td>
</tr>
</tbody>
</table>

Table 3. Identification each branch (Event) in $T$

Table 4. Transformed database

Then, the extraction of frequent sequences can be carried out. With $\sigma = 0.75$, the pattern $\{e_3\} \{e_2\}$ is frequent. This sequence transforms to $\{(UH_{Paris}, C_1), \{p_1, p_2\}\}, (GH_{Lyon}, R_1), \{p_2\})$ by using the identification in Table 3.
4 Experiments

We conduct experiments on both real and synthetic datasets. The algorithms is implemented in Java and the experiments are carried out on a MacBook Pro with a 2.5GHz Intel Core i5, 4GB of RAM Memory running OS X 10.6.8. The extraction of sequential patterns is based on the public implementation of CloSpan algorithm [9]. We use the implementation supplied by the IlliMine\(^5\) toolkit.

In order to assess the effectiveness of our approach, we run several experiments on the PMSI dataset. This database includes the following informations: Patients (id, gender . . .), Stays (id, hospital, principal diagnosis, . . .) and Medical Procedures (id, date,. . .). Our dataset contains 486 patients suffering from lung cancer and living in the eastern region of France. The average length of data sequences is 27. The data is encoded using controlled vocabularies. In particular, diagnoses are encoded with the International Classification of Diseases (ICD10)\(^6\). This classification is used as an input taxonomy for MMISP. The ICD10 can be seen as a tree with two levels. As illustrated in Figure 6, 3-characters codes such as C34 (Lung cancer) have specializations: C340 is cancer of the main bronchus, C341 is cancer of upper lobe etc.

<td>(((C391, 210780136), {YYYY030}), ((C07, 210780136), {ZBQK002}), . . .)</td>
</tr>
</tbody>
</table>

Table 5 is an example of care trajectories described over two dimensions (diagnosis, hospital ID) coupled with a set of medical procedures. For example (C341, 750712184), \{ZBQK002\} represents the stay of a patient in the University Hospital.

---

\(^5\) http://illimine.cs.uiuc.edu/

\(^6\) http://apps.who.int/classifications/apps/icd/icd10online/
sity Hospital of Dijon (coded as 210780581) treated for a lung cancer (C341), where the patient underwent chest radiography (coded as ZBQK002).

The experiments are designed to extract some multi-dimensional sequential patterns for helping the medical experts to describe some healthcare patients trajectories. For this experiment the support value is set to 15 (i.e. $\sigma = 0.03$). MMISP generates 121 different patients trajectories. Table 6 shows some patients trajectories obtained by our approach. Pattern 2 can be interpreted as follows: 42% of patients have a hospitalization in the University Hospital of Dijon for a lung cancer (210780581,C341), where they underwent supplement procedures (coded as YYYY030) for passing the chest radiography (coded as ZBQK002). Then, the same patients go to any university hospital for doing chemotherapy (CHU/CHR,Z511), where they underwent only the chest radiography (coded as ZBQK002).

</table>

Table 6. Some healthcare patients trajectories obtained by MMISP

![Fig. 7. Running Time (left) and Number of extracted pattern (right) obtained by MMISP with varying in the number of dimension](image)

In the second experiments, we study the scalability of our approach. We consider the number of extracted patterns and the running time with respect to two different parameters, the number of the dimension in the multidimensional
components and the average length of the itemsets in the data sequences. The first batch of synthetic data generated contains 10,000 sequences defined over (2, 3, 4 and 5) analysis’ dimensions. Each sequence contains 30 events and each event is described, in average, by 15 items in the itemset. Hierarchical relations are defined over 5 levels of granularity between elements of each analysis dimension. Figure 7 reports the results according to different values of support threshold for different number of analysis dimension in multidimensional component. We can notice that the running time increases for each newly added analysis dimension. The second batch of synthetic data generated contains 10,000 sequences with varying number of items 5, 10, 15 and 20. The sequences in the four generated data sets have an average cardinality of 30 events, by 3 analysis dimensions. Hierarchical relations are defined over 5 levels of granularity between elements of each analysis dimension. Figure 8 reports the results according to different values of support threshold for different lengths of itemsets.

Fig. 8. Running Time (left) and Number of extracted pattern (right) obtained by MMISP with varying itemsets’ cardinalities

5 Conclusion

In this paper, we propose a new approach to mine multi-dimensional itemset sequential patterns. Our approach is able to capture knowledge from dataset represented over both multi-dimensional component and itemsets. We provide formal definitions and propose a new algorithm MMISP to mine this new kind of pattern. We conduct experiments on both real and synthetic datasets. The method was applied on real-world data where the problem was to mine healthcare patients trajectories. According to medical experts, new patterns are easier to understand.
