Abstract

This paper presents a generic solution to apply a mission described by a sequence of task on a robot while accounting for its physical constraints, without computing explicitly a reference trajectory. A naive solution to this problem would be to schedule the execution of the tasks sequentially, avoiding concurrency. This solution does not exploit fully the robot capabilities such as redundancy and have poor performance in terms of execution time or energy. Our contribution is to determine the time-optimal realization of the mission taking into account robotic constraints that may be as complex as collision avoidance. Our approach achieves more than a simple scheduling; its originality lies in maintaining the task approach in the formulated optimization of the task sequencing problem. This theory is exemplified through a complete experiment on the real HRP-2 robot.

Introduction

A robot is designed to perform missions in various application contexts. When the environment is well or partially structured most missions can be hierarchically decomposed into a set of tasks (i.e., generic sensory-motor functions) which has to be mapped into robot execution. Numerous works have been proposed to compute such a sequence of tasks from a given mission and a set of causal paradigms (Dechter 2003; Ghallab, Nau, and Traverso 2004). However, they generally produce a symbolic plan, where the only numerical precisions lie on the scheduled time data. Moreover, constraints have to be expressed under a symbolic expression. Its robotic application into the real world requires the time sequence to be refined, typically through an applicative path planner (LaValle 2006), that will compute the trajectories to be followed by the robot (Lamare and Ghallab 1998). Yet, the meaning of the symbolic plan is lost in the global trajectory. Such low-level methods lack of robustness to environment changes or uncertainties. Consequently, the remaining trajectory may have to be recomputed several times while the mission is being achieved. Moreover, it is difficult (and often specifically hard coded) to enhance the trajectory with symbolic data, that would help re-computing only part of the plan (Py and Ingrand 2004) or distort locally the trajectory after small environment changes (Quinlan and Khatib 1993).

Rather than using a trajectory planner between the temporal reasoning and its real robotic execution, we propose to use a sensory-motor control approach based on task components. The task function (Samson, Le Borgne, and Espiau 1991) is an elegant approach to produce intuitively sensor-based robot objectives. Based on the redundancy of the system, the approach can be extended to consider a hierarchical set of tasks (Siciliano and Slotine 1991). Hierarchy of tasks are becoming popular to build complex behavior for very redundant robot such as humanoid (Mansard and Chaumette 2007; Sentis and Khatib 2006).

A task (i.e., a task function) can be directly linked to the symbols on which the task temporal network is reasoning. Mission decomposition is thus executable directly using the sensory-motor mapping of the task function. However, exclusive task sequencing on the robot produces generally jerky suboptimal movements which may look to humans as monotonous automated motions. This paper focuses on finding a solution to produce automatically an optimal plane/schedule that makes use of the redundancy by enabling task concurrency. It seems difficult to use temporal networks to produce a scheduling with task overlapping when the tasks concurrency is restricted by physical limitations of the robot (for example obstacles or balance of a biped robot), since the constraints are not in a discreet form. On the other hand, semi-infinite optimization (Lee et al. 2005) is known to generate low level trajectories, while accounting for such constraints, but with insufficient robustness to environment uncertainties.

In this paper, we propose to rely on task for both the symbolic reasoning and control of the robot. In between, we propose to use semi-infinite optimization to refine the symbolic schedule and account for system constraints. Given a sequence of tasks to achieve a mission, our solution returns for each task the optimal times at which it is activated and inactivated and the optimal parameters for the task execution. The originality of our approach lies in keeping the task component in the formulation of this problem, which can roughly translate to optimizing tasks overlapping by manipulating tasks, i.e., the controllers as variables of the optimization problem.
**Generic Task Sequencing**

**Task function formalism and Stack of Tasks**

Defining the motion of the robot in terms of task simply consists in choosing several control laws to be applied on a subpart of the robot degrees of freedom (DOF). A task is defined by a vector \( e \) (typically, the error between a signal \( s \) and its desired value, \( e = s - s^* \)). The Jacobian of the task is noted \( J = \frac{\partial e}{\partial q} \), where \( q \) is the robot configuration vector. In the following, we consider that the robot input control is the joint velocity \( \dot{q} \). Considering a reference behavior \( \dot{e}^* \) to be executed in the task space, typically,

\[
\dot{e}^* = -\lambda e,
\]

the control law to be applied on the robot whole body is given by the least-square solution:

\[
\dot{q} = J^+ \dot{e}^* + P z
\]

where \( J^+ \) is the least-square inverse of \( J \), \( P = I - J^+ J \) is the null-space of \( J \) and \( z \) is any secondary criterion. \( P \) ensures a decoupling of the task with respect to \( z \), which can be extended recursively to a set of \( n \) tasks, each new task being fulfilled without disturbing the previous ones:

\[
\dot{q}_i = \dot{q}_{i-1} + (J_1 P^A_{i-1})^+ (e_1 - J_1 \dot{q}_{i-1}), \quad i = 1 \ldots n
\]

where \( \dot{q}_0 = 0 \) and \( P^A \) is the projector onto the null-space of the augmented Jacobian \( J^A = (J_1, \ldots, J_1) \). The robot joint velocity realizing all the tasks in the stack is \( \dot{q} = \dot{q}_n \).

A complete implementation of this approach is proposed in (Mansard and Chaumette 2007) under the name *Stack of Tasks* (SoT). The structure enables to easily add or remove a task, or to swap the priority order between two tasks, during the control. Constraints (such as joints limit) can be locally taken into account. The continuity of the control law is preserved even at the instant of change.

**Gain handling**

The simple attractor presented in (1) produces a nice exponential decrease. However, it also produces a strong acceleration at the beginning of the task, while at the end of the task, \( \|e\| \) decreases slowly (slow convergence). A very classical ‘trick’ when regulating a task is to rather use an adaptive gain \( \lambda = \lambda(e(t)) \), for example:

\[
\lambda(e) = (\lambda^F - \lambda^I) \exp(-\|e\| / \beta) + \lambda^I
\]

with \( \lambda^I \) the gain at infinity, \( \lambda^F \) the gain at regulation (\( \lambda^I \leq \lambda^F \)) and \( \beta \) the slope at regulation.

**Sequence of tasks**

A task sequence is a finite set of tasks sorted by order of realization, and eventually linked to each other. Any pair of tasks can be either independent (i.e. they can be achieved in parallel), or constrained (i.e. one may have to wait for another one to be achieved, in order to make sense or to be doable). The sequence can be formulated into a classical temporal network scheduling, starting at \( t^0 \) and ending at \( t^{End} \). Both values are finite and the sequence does not loop. Besides, we may consider for the sake of clarity but without loss of generality that each task appears only once.

The *position* of a task in the sequence is defined by the time interval during which it is maintained in the SoT. For a given task \( i \), this interval is noted \([t_i^I, t_i^F]\), defined with respect to \( t^0 \). The regulation time \( t_i^R \) is defined by \( \|e_i(t_i^R)\| = \epsilon_i \), with \( \epsilon_i \) the tolerance upon task realization.

A task sequence is characterized by a set of time-constraints binding the schedules of two tasks \( e_1 \) and \( e_2 \). They can be defined as follow:\(^1\) \( e_1 \) must begin or end once \( e_2 \) has begun, has ended or has been regulated. We use the following notation to describe the sets of pairs of tasks \( e_1 \) and \( e_2 \) that undergo these dependencies (\( e_1 \) is the direct predecessor of \( e_2 \)):

\[
S_{I, I} = \{(e_1, e_2) | t_i^I \leq t_i^F \}
\]

\[
S_{R, I} = \{(e_1, e_2) | t_i^R \leq t_i^F \}
\]

\[
S_{R, F} = \{(e_1, e_2) | t_i^R \leq t_i^F \}
\]

\[
S_{F, I} = \{(e_1, e_2) | t_i^R \leq t_i^F \}
\]

\[
S_{F, F} = \{(e_1, e_2) | t_i^F \leq t_j^F \}
\]

**Continuous optimization of sequence of tasks**

Given a set of hypothesis described using (5), a generic solution is now proposed to automatically compute the optimal task and schedule parameters to be executed by the SoT.

**General problem formulation**

An optimization problem is composed of a criterion to minimize, along with a set of variables and equality and inequality constraints to be satisfied. Our criterion is the total duration of the mission. The variables are: (i) the times \( t_i^I \) and \( t_i^F \) and (ii) the gains \((\lambda^I, \lambda^F, \beta)\). The general optimization problem is written as follows:

\[
\min_{x} t^{End}
\]

subject to \( \dot{q} = SoT_{x}(q, t) \)

\( \|e\| < 0 \)

\( \phi(q) < 0 \)

\( \forall i, t_i^F \leq t^{End} \)

with \( x = [t_1^I, t_1^F, \lambda_1^I, \lambda_1^F, \beta_1, \ldots, t_n^I, t_n^F, \lambda_n^I, \lambda_n^F, \beta_n, t^{End}] \) the set of optimization variables of each task, \( t^{End} \) the duration of the mission, and seq\(\{q\}\) and \( \phi(q) \) the sequencing and robotic constraints.

**Constraint definitions**

Parameters \( x \) must satisfy both the sequencing and the robotic time-constraints enumerated hereafter:

**Tasks constraints, noted seq\(\{q\}\) are defined as follow:**

- Time coherence for each task \( i \), that is:

\[
\forall i, 0 \leq t_i^I < t_i^F \leq t^{End}
\]

---

\(^1\)contrary to Allen Logic, that only considers the start and end date, here is also considered the regulation time \( t^R \).
*****

- Termination condition for each task $i$, that is:
  \[ \forall i, \|s^*_i - s_i(t^F_i)\| < \epsilon_i \]  

- Task sequence conditions for any couple of tasks $i$ and $j$:
  \[ \forall (i,j) \in S_{I,I}, t^I_i \leq t^I_j \]  
  \[ \forall (i,j) \in S_{F,F}, t^F_i \leq t^F_j \]  
  \[ \forall (i,j) \in S_{F,I}, t^I_i \leq t^F_j \]  
  \[ \forall (i,j) \in S_{R,I}, t^R_i \leq t^I_j \]  
  \[ \forall (i,j) \in S_{R,F}, t^R_i \leq t^F_j \]  

- Gain consistency for each task $i$, namely:
  \[ \forall i, \lambda^I_i \leq \lambda^F_i \]  

The constraints (7), (9), (10), (11) and (14) are linear. On the contrary, the constraint (8) is impossible to compute directly using $x$, and is determined from a simulation of the execution. Care has to be taken while resolving the condition described by (12) and (13). Indeed, discretizing $t^R$ to the closest simulation step will produce discontinuities which may disturb the optimization process. The constraint (12) and (13) are thus equivalently rewritten:

\[ \forall (i,j) \in S_{R,I}, \|s^*_i - s_i(t^I_j)\| \leq \epsilon_i \]  

\[ \forall (i,j) \in S_{R,F}, \|s^*_i - s_i(t^F_j)\| \leq \epsilon_i \]

**Robot constraints**: $\phi(q)$ Those constraints are mainly due to hardware intrinsic limitations of the robot:

- Joint limits, given by
  \[ q_{\text{min}} \leq q \leq q_{\text{max}} \]  

$q_{\text{min}}$, $q_{\text{max}}$ are the lower and upper joint limits.

- Velocity limits, given by
  \[ q_{\text{min}} \leq \dot{q} \leq q_{\text{max}} \]  

$q_{\text{min}}$, $q_{\text{max}}$ are the minimal and maximal velocity.

- Collision between a given pair of objects $i$ and $j$, given by
  \[ d_{ij} \geq 0 \]  

$d_{ij}$ is the distance between objects $i$ and $j$. Object designate those found in the mission environments and each link of the robotic system. Hence, both collision with the environment and self-collision of the robot have to be evaluated.

It can be shown that (6) defines a continuous optimization problem. However, $q$ is in fact a vector of functions of time, hence constraints $\phi(q)$ are semi-infinite, i.e. taking place for all the values of the continuous variable $t \in [t^I, t^F]$. Care have thus to be taken when implementing them in classical solver softwares.

### Optimization

At each optimization step, the solver chooses a new set of parameters $x$. It then computes the constraints. Constraints (7), (9), (10) and (14) can be evaluated directly. As stated previously, the other constraints can not be directly computed (since they do not write in an analytical explicit formulation). They are thus evaluated using a complete simulation of their execution. The chosen value of the current optimization variable vector $x$ is transmitted by the solver to a simulation engine. The simulation returns the evaluation of the constraints and the optimization solver computes a new step vector $x$, until convergence.

### Simulation

The simulation is basically a numerical integration of (6) using an explicit Euler integration method with a fixed step $\Delta t = 0.005$ sec. The times $t^I_i$ and $t^F_i$ are continuous variables that may not be aligned with the integration grid, and have to be explicitly added to ensure continuity with respect to the optimization variables. The simulation engine runs under the AMELIF framework (Evrard et al. 2008), an interactive dynamic simulator for virtual avatars which includes collision detection and task handling according to the SoT formalism. The execution for both simulation and real-robot control is performed by a generic control framework based on (Mansard et al. 2009).

### Experiment

#### Temporal network

The experiments have been realize using a pick-in-box scenario: the robot has to open the fridge with one hand before grasping the object with the other hand. Similarly, it has to wait for the grasping to be completed before closing the fridge. Instead of explicitly defining these causal constraints, we simply consider the collision detection to ensure the causality. The optimal schedule should use the system redundancy by overlapping the tasks on each arm.

The task sequence is composed of 10 tasks (see Fig.1):

- $e_0$ - open the right gripper
- $e_1$ - move the right arm to the fridge
- $e_2$ - close the right gripper
- $e_3$ - open the fridge
- $e_4$ Close the fridge
- $e_5$ - open the left gripper
- $e_6$ - move the left gripper in the fridge area
- $e_7$ - move the left gripper to the can
- $e_8$ - close the left gripper
- $e_9$ - lift the can
- $e_{10}$ - remove the can out of the fridge.

This mission can not be split into smaller independent sequences. The constraints considered for this problem are thus sequencing and robotic constraints (joint position and velocity limits), and non-colliding with the fridge.

### Results of the optimization

The optimization ran on a 3GHz desktop PC running under Windows OS, using MATLAB SQP solver. The sequence found is described on Fig. 2. The overlaps between the tasks of each arm appear clearly: the left arm starts moving before the fridge is open. It then starts the reaching motion even if the fridge is not completely open. The right arm starts to
close the fridge before the left arm has completely left the fridge area. The whole task sequence lasts 47sec. Without these two overlaps, the optimal timing will only be 71sec.

The SoT formalism allows to directly apply the optimized task sequence as a control law using the same task definition. The task sequence is executed by the robot HRP-2, a full-size humanoid robot with 30 actuated DOF. For the tasks requiring a haptic interaction (i.e. opening and closing the fridge) the force sensor of the robot is used to close the loop and compensate for position uncertainties. The robot manages to grasp the can without constraint violation, in a smooth manner thanks to the optimized gain. Snapshots of the execution are given in Fig. 3. See http://www.laas.fr/~fkeith/keithfridge.avi for the video of the complete execution.

Conclusion

We devise a method which allows to automatically pass from a symbolic plan to a complete motion generator that takes into account all kind of robot constraints, such as joint limits or collision. The result optimize both the behavior and the overlapping scheduling of a sequence of tasks composing a robotic mission. The solution derives from an optimization formulation of the tasks scheduling keeping the formalism built on the top of a task-function based control. The solution is generic, and may applied to any problem of motion generation based on a schedule of tasks under continuous semi-infinite constraints, while optimizing various criteria.
