Abstract—In this paper, we study the distance-2 broadcast scheduling problem in synchronous wireless networks of known topology. Two constraints are taken under consideration: the schedule must be collision-free and the nodes at distance 2 must be informed by nodes at distance 1. In general graphs, a tight bound of $O(\log(n)^2)$ slots to complete the broadcast is known, $n$ being the number of nodes at distance 2. We improve this bound to $O(\log(n))$ in unit disk graphs, and to $O(1)$ when the neighbourhoods of the nodes are circular intervals.

I. INTRODUCTION

We consider the communication model proposed by [1] in which nodes communicate at synchronous slots, using only one frequency. When a node transmits at a given slot, all the nodes connected to it may receive the message. Collisions occur when a node receives several messages at the same slot. Collisions cannot be detected. When exactly one of its neighbours transmits at a given slot, a node is said to be informed.

We study the distance-2 broadcast scheduling problem (D2B) when the topology of the graph is known in advance. Given a graph and a source node, one must schedule the roles of the nodes over several slots in order to inform every node at distance 2 from the source. We assume that nodes at distance 2 from the source cannot be used to inform other nodes. We quantify the quality of a scheduling by the number of slots it uses, the less the better. The number of slots used is an intuitive measure of the time taken to complete the broadcast. This problem is motivated by the fact that knowledge at distance 2 is often assumed when designing communication protocols.

A. Related work

This work is primarily inspired by [2], [3], dealing with D2B in general graphs. They give polynomial algorithms to schedule distance-2 broadcasts using $O(\log(n)^2)$ slots, where $n$ is the number of nodes at distance 2 from the source. Their result provides a tight upper bound on the number of slots needed to complete broadcast since there exists a family of graphs of diameter 2 requiring a logarithmic number of slots to complete broadcast.

The global broadcast problem, in which a source must flood the whole network, has been widely studied in general graphs. See [4] for a survey.

On a theoretical point of view, solving D2B under the collision model is linked to the exact cover problem. Authors in [5] give a polynomial algorithm to solve the weighted covering problem for sets of pseudo-disks in the plane. Their algorithm can be adapted to decide the existence of a 1-slot solution to D2B on unit disk graphs.

B. Our results

Our work focuses on restricted classes of graph, and show that the upper bounds in those cases are strictly lower.

First, we exhibit a family of instances over unit disk graphs such that solving D2B requires exactly $\log(n) + 1$ slots, $n$ being the number of nodes at distance 1 from the source. We further prove that it is always possible to complete broadcast using $O(\log(n))$ slots, tightening the bound.

Then we consider a more restrictive case: when the neighbourhoods of the nodes at distance 1 are circular arcs of the nodes at distance 2. We give a simple greedy algorithm yielding solutions using at most 3 slots. This algorithm proves a constant upper bound on the number of slots needed to complete distance-2 broadcasts in these graphs.

C. Notations

An instance of the distance-2 broadcast scheduling problem (D2B) is given by a graph $G = (V, E)$ and a node $x_e$ of this graph. The immediate neighbours $X$ of $x_e$ are called the source nodes. We call target nodes the set of nodes $Y$ at distance 2 from $x_e$. This terminology is motivated by the fact that nodes from $Y$ cannot be scheduled in the broadcast. Assuming so, solving D2B then consists in scheduling the transmission of some nodes in $X$ such that every node in $Y$ gets informed at some slot. A solution to D2B is a set of subsets of $X$, $\{X_1, \ldots, X_k\}$, $k$ being the number of slots the solution uses.

It is clear that $X$ can be fully informed in one slot when $x_e$ acts as the sole transmitter, the bounds we prove in the following do not count this trivial step.

II. UNIT DISK GRAPHS

In this section, $D_r$ denotes the unit disk centred at the origin. We can assume without loss of generality that the source node $x_e$ is at the origin. When a disk is referred to as $D_i$ for some label $i$, then $C_i$ will be the corresponding circle i.e. the border of $D_i$. 

Let us assume that the nodes lie on a plane and that each source node has a communication disk - its source disk. Target nodes must be covered using these disks. An instance of D2B is now a couple $(D, Y)$, $D$ being a set of source disks and $Y$ a set of targets. Let $D = \{D_1, \ldots, D_m\}$ be a set of labelled source disks. Given $D' \subseteq D$, the proper intersection of all the disks in $D'$ is $\cap_{D'} := \bigcap_{x \in D'} x \setminus \bigcup_{y \in D \setminus D'} y$. If said proper intersection is non-empty, we say that $D'$ induces a target area. We define the signature of a target area as the set containing all the labels of the disks inducing this area.

In Figure 1, three disks $D_1, D_2, D_3$ intersect each other. The gray areas are target areas. Each area has a signature. For instance the target area of signature $(1, 2)$ is the intersection between $D_1$ and $D_2$ minus $D_3$. Note that the target areas partition the union of all the disks.

A. Unit disk graphs requiring a logarithmic number of slots

**Theorem II.1.** Let $m \in \mathbb{N}$. Let $D = (D_1, \ldots, D_m)$ be a set of distinct source disks which centres lie on the same radius of the unit disk. There exists a set $Y$ of points such that solving D2B over $(D,Y)$ requires $1 + \lceil \log_2(|Y|) \rceil$ slots.

**Proof.** We can assume that $D$ is ordered by the disks’ centres’ distance to the origin. For all $D_i$ in $D$, $x_i$ is the centre of $D_i$. The signature matrix $M$ given in Figure 2 contains the signatures of all the non-empty target areas induced by $D$.

Now we build an instance of D2B by placing a target node in each target area. Denote $n$ the number of target nodes ($n = \frac{m(m+1)}{2}$) and $l_k$ the number of slots needed to inform $k$ targets for all $k \in \{1, \ldots, n\}$. Clearly $l_1 = 1$.

For some $i$, let us remove from $M$ all the target areas which signatures contain $i$ (see the gray part in Figure 3). Note that the remaining areas to cover may form two disjoint instances—residual instances—of the problem on smaller graphs. One instance uses disks of indexes $1$ to $i-1$ and the other uses disks of indexes $i+1$ to $m$. Note that if $i = 1$ or $i = m$, there is only one residual instance.

![Fig. 2.](image-url)  
Fig. 2. Signature matrix $M$. Each entry is the signature of a target area induced by $D$. Note that an entry $(i, j)$ corresponds to the signature $(i, \ldots, j)$.

Observe that the signature matrices of the residual instances have the same form as the original instance. Whichever $i$ is chosen to emit at first slot, at least one of the residual matrices has size at least $\lceil \frac{m-1}{2} \rceil$. Since the two residual instances are disjoint, they can be processed in parallel. The following recurrence on $t_n$ is now verified.

$$t_n \geq t_{\lceil \frac{n-1}{2} \rceil} + 1 \geq 1 + \lceil \log_2(n) \rceil$$

Now let us prove that the recurrence equation can be tight. The two following properties are verified.

1) There exists a target area of signature $(1, \ldots, m)$. In any solution $(X_1, \ldots, X_k)$ there is thus a $X_i$ of cardinality 1.

2) Given a solution $(X_1, \ldots, X_k)$, permuting two sets in the solution does not change it.

Taking these two facts under account, we can assume that in any solution the first slot is occupied by a single source node $i.e. |X_1| = 1$.

Now if we choose the central node $i = \lceil \frac{m-1}{2} \rceil$ to transmit at each recursion step, then the solution produced is necessarily optimal. Indeed, in each residual instance the target area with the biggest signature has to be covered. By choosing the central node as sole transmitter for the first step, we ensure that said area is covered, and that the residual instances have roughly the same size. We then have $t_n = 1 + \lceil \log_2(n) \rceil$.

B. A logarithmic number of slots always suffices

We call angular region any part of the plane delimited by two half-lines with a common extremity being the origin. An
Let \( D \) be a set of source disks, and \( Z \) be an angular region of angle \( \frac{\pi}{2} \). For all \( D_1, D_j \) in \( D \), \( C_1 \) and \( C_j \) intersect at most once in \( Z \setminus D_u \).

**Lemma II.1.** Let \( D \) be a set of source disks, and \( Z \) be an angular region of angle \( \frac{\pi}{2} \). For all \( D_1, D_j \) in \( D \), \( C_1 \) and \( C_j \) intersect at most once in \( Z \setminus D_u \).

**Proof.** Let \( D_1 \) and \( D_2 \) be two disks of centres \( A \) and \( B \), containing the origin \( O \). Let \( P \) and \( Q \) be the intersection points between \( C_1 \) and \( C_2 \). Let \( C \) be the intersection between the line \( (OA) \) and \( D_1 \). We can assume without loss of generality that \( A \) and \( B \) lie in a half of the unit disk centred in \( O \). We can also assume that \( A \) is closer to \( O \) than \( B \) is. Now let \( \alpha \) be the angle \( (\overrightarrow{OP}, \overrightarrow{OQ}) \), \( \beta \) the angle \( (\overrightarrow{AQ}, \overrightarrow{AP}) \) and \( \gamma \) the angle \( (\overrightarrow{CP}, \overrightarrow{CQ}) \) (see Figure 4). Since \( \beta \) and \( \gamma \) intercept the same arc of \( C_1 \), the angle at center theorem states that \( \gamma = \frac{\alpha}{2} \).

By construction, since the triangle \( OPQ \) is contained in the triangle \( CPQ \), we have \( \alpha \geq \gamma \). Then, \( \beta > \pi \) because if \( \beta = \pi \) then \( PQ \) is a diameter of both \( C_1 \) and \( C_2 \) meaning that these two circles are equal. We thus have \( \alpha > \frac{\pi}{2} \) and therefore \( C_1 \) and \( C_2 \) cannot intersect more than once in \( Z \setminus D_u \).

Given a set of source disks \( D \) and a disk \( D \in D \) labelled \( i \) we say that \( D \) induces a proper area if there exists a target area induced by \( D \) of signature \((i)\). Now consider an angular region \( Z \) of angle \( \frac{\pi}{2} \), we define \( D_{|Z} \) as the set of all disks in \( D \) intersecting \( Z \) non-empty. We then remove from \( D_{|Z} \) all the disks not inducing a proper area in \( Z \). Now order the disks in \( D_{|Z} \) according to the angle to the proper area they induce (see Figure 5). After this ordering \( D_{|Z} = (D_1, \ldots, D_n) \) if \( S_i \) and \( S_j \) are proper areas induced by \( D_i \) and \( D_j \) with \( i < j \) then \( \forall P \in S_i, \forall Q \in S_j, (\overrightarrow{OP}, \overrightarrow{OQ}) \in [0, 2\pi[ \).

We will next assume that \( D_{|Z} \) does not contain three circles intersecting in one point in \( Z \). It is not hard to work around it, but simplifies the proof of the following lemma.

**Lemma II.2.** Let \( S \) be a target area induced by \( D_{|Z} \) such that \( S \cap Z \neq \emptyset \) then the signature of \( S \) is of the form \( \sigma(S) = (i, i + 1, \ldots, i + p) \) for some \( i, p \).

**Proof.** Let us assume it is not the case, thus there is a gap in the signature of \( S : \sigma(S) = (i, \ldots, k, k + j, \ldots, i + p) \) with \( j > 1 \). Consider the set of source disks \( D' = \{D_k, D_{k+1}, D_{k+2}\} \) which we can renumber \( D'' = \{D_1, D_2, D_3\} \) to clarify things. Now there exists an area of signature \((1, 3)\). Using Lemma II.1 we know that there is a unique intersection point \( P \) between \( C_1 \) and \( C_2 \) in \( Z \). Let \( Z^- \) (resp. \( Z^+ \)) be the part of \( Z \) located counterclockwisely before (resp. after) the line \((OP)\). Let \( D^+_i := D_i \cap Z^+ \) and \( D^-_i := D_i \cap Z^- \) for \( i = 1, 2, 3 \). Since \( C_1 \) intersects \( C_2 \) only once, we know that \( D^-_2 \subset D^+_1 \) and \( D^+_3 \subset D^-_2 \). As a consequence, the area of signature \((1, 3)\) cannot lie in \( Z^+ \), it has to lie in \( Z^- \).

1. Assume that \( C_1 \) and \( C_3 \) do not intersect in \( Z^- \), then \( D^-_3 \subset D^+_1 \) because otherwise the proper area induced by \( D_3 \) appears before the proper area induced by \( D_1 \), which is absurd. Note that \( C_2 \) and \( C_3 \) have to intersect in \( Z^+ \) because if not

   a) either \( D^+_3 \subset D^-_2 \) and then \( D_2 \) does not induce a proper area in \( Z \) since \( D^-_2 \subset D^+_1 \), which is absurd;

   b) or \( D^+_3 \subset D^-_2 \) and then the proper area induced by \( D_3 \) appears in \( Z^- \) thus before the one induced by \( D_2 \) which lies in \( Z^+ \), That is absurd as well.

Thus, \( C_2 \) crosses \( C_3 \) in \( Z^+ \) and we know they do not intersect in \( Z^- \) using Lemma II.1. Under these assumptions \( D^-_3 \subset D^+_2 \) because otherwise \( D^-_3 \subset D^+_2 \) and \( P \in D^-_3 \), thus \( D^-_3 \cap D^+_1 \neq \emptyset \) or \( D^-_3 \subset D^+_1 \), in both cases it is absurd. Thus, we have \( D^-_3 \subset D^+_2 \), and in that case the area of signature \((1, 3)\) cannot exist, which is absurd since we assumed it did exist.

2. Finally, assume that \( C_1 \) and \( C_3 \) do intersect in \( Z^- \). Then \( C_3 \) intersects \( C_1 \) before \( P \) (because we assume that three circles never intersect in one point) and the proper area induced by \( C_3 \) appears before the proper area induced by \( C_2 \), absurd again.
Both cases lead to contradictions, the area of signature (1, 3) cannot exist. The signature of $S$ is thus of the form $(i, i + 1, \ldots, i + p)$, thus the lemma.

**Theorem II.2.** Let $D$ be a set of source disks, then all the target areas induced by $D$ can be covered using $O(\log_2(n))$ slots.

**Proof.** Partition the plane in four angular sectors of angle $\frac{\pi}{2}$, $Z_1, Z_2, Z_3, Z_4$. First, consider $Z_1$ then using Lemma II.2 any target area appearing in $Z_1$ has signature of form $(i, i + 1, \ldots, i + j)$ for some $i, j$ (after removing the disks not inducing proper areas and reordering $D_{|x_i}$). We can thus build a signature matrix for $D_{|x_i}$ having the same form as the matrices considered in subsection II-A. Since we showed that instances with such signature matrices can be dealt with using $O(\log_2(n))$ slots, we can cover any target area appearing in $Z_1$ using $O(\log_2(n))$ slots. We can then do the same for $Z_2, Z_3$ and $Z_4$ sequentially and cover any target area induced by $D$ in $O(\log_2(n))$ slots.

**III. Circular arc neighbourhoods**

We now suppose that the set $Y$ of target nodes can be placed on a circle, and the neighbourhoods of $Y$ can be represented by proper arcs on that circle - that is a target node $y$ can be reached by a source node $x$ if $y$ lies on the arc representing $x$’s neighbourhood. For instance, on Figure 6, $x_1$ has neighbourhood $\{y_1, y_2, y_3, y_4\}$.

$X$ and $Y$ can be arbitrarily ordered as follows. Pick one of the source nodes $x$ to be the first one in the $X$ order ($x = x_1$), then number $\{y_1, \ldots, y_k\}$ its neighbours. Now number $x_2$ the node which arc starts after $x_1$, and its neighbours can be numbered following $x_1$’s neighbours. One can do so until every node in $X$ and every node in $Y$ have been ordered (see Figure 6).

![Figure 6](image_url)

Fig. 6. Dots are target nodes, arcs represent source nodes

**Theorem III.1.** 3 slots are always enough to solve $D2B$ in the circular arc neighbourhoods case.

**Proof.** The following procedure produces a solution to $D2B$ using at most 3 slots.

1) order $X$ and $Y$ as previously explained
2) let $y$ be the first target in $Y$ not yet covered
3) add to the solution the arc covering $y$ ending the furthest possible after $y$
4) go to 2 while $Y$ is not entirely covered

Denote $x_1, \ldots, x_k$ the nodes selected during the procedure. Then $N(x_i) \cap N(x_{i+2}) = \emptyset$ for all $i = 1, \ldots, k - 3$. Indeed, if $N(x_i) \cap N(x_{i+2}) \neq \emptyset$ then consider the target $y$ that forced the algorithm to pick $x_{i+1}$, and the target $y'$ that made it pick $x_{i+2}$. We know that $y \notin N(x_i)$, and that the arc $x_{i+1}$ ends after the arc $x_{i+2}$ (otherwise $x_{i+2}$ would have been picked instead since $N(x_i) \cap N(x_{i+2}) \neq \emptyset$), but then $y'$ being the first target after $x_{i+2}$ would be contained in $N(x_{i+1})$ and $x_{i+2}$ would not have been picked, that is absurd thus $N(x_i) \cap N(x_{i+2}) = \emptyset$.

Possibly $N(x_{k-2}) \cap N(x_k) \neq \emptyset$. Now, let $X_1 = \{x_i, i < k \text{ is odd}\}$, $X_2 = \{x_i, i < k \text{ is even}\}$ and $X_3 = \{x_k\}$. $\{X_1, X_2, X_3\}$ is thus a broadcast using three slots.

**IV. Conclusion**

We studied the distance-2 broadcast problem in two specific cases. In general graphs, there is a tight $O(\log(n))^2$ upper bound on the number of slots needed to solve the problem. We improved this bound in unit disk graphs to $O(\log(n))$. In the case the neighbourhoods can be represented as circular intervals, we proved the bound to be even lower: $O(1)$.

In the future we would like to extend our research to other classes of graphs, or more accurate communication models. Another interesting problem is the maximal cover in a fixed number of slots.
