Abstract. The problem of verifying the absence of collision between a cable and the mobile part(s) of a device located on-board the mobile platform of a Cable-Driven Parallel Robot (CDPR) is addressed. The set of all positions taken by one cable of the CDPR for all the poses of the mobile platform in a prescribed workspace is called the cable span. A simple bounding volume approximation of the cable span is proposed in this paper. This bounding volume is a polyhedron and the characterization of the faces of this polyhedron is discussed. Using this polyhedron as a bounding volume of the cable span allows to accelerate computations related to collision avoidance checking.

Keywords: Cable-Driven Parallel Robot, Cable, Span, Collision

1 Introduction

Cable-Driven Parallel Robots (CDPRs) consist of a mobile platform driven by cables. Using cables instead of rigid links gives CDPRs interesting characteristics such as a potentially very large workspace, large payload-to-weight ratio, and high dynamics capabilities.

However, one of the major drawbacks of CDPRs is their low stiffness due to the use of cables. This low stiffness may be the cause of vibrations affecting the platform positioning accuracy. Several techniques can be used to damp these vibrations: input shaping [1], modal space control [2], or active damping by creating a transient wrench to compensate the vibrations. This wrench can be created by additional actuated stabilizing mechanical devices placed on board the mobile platform [3–6]. In reference [5], a stabilizer consisting of rotating arms is located on-board the CDPR mobile platform to actively damp vibrations, as illustrated in Figure 1. The work reported in the present paper is part of a project aiming to embed a similar stabilizer on the platform of the 6 Degree-of-Freedom (DOF) CDPR CoGiRo [7], shown in Figure 2.

The design of CoGiRo ensures that there is no cable-cable collision nor cable-platform collision within the workspace of this CDPR. However, when active mechanical devices are placed on-board the CDPR mobile platform, the moving parts of these on-board devices may collide with the cables or platform. This eventuality of collisions is an issue that must be taken into account in the design

Fig. 1: Planar 3-DOF CDRP with 3 stabilization arms

Fig. 2: 6-DOF CDRP CoGiRo

optimization of on-board active devices. In order to prevent such collisions, a first step is to determine the volume of space occupied by each cable when the CDRP platform moves throughout a given workspace. Indeed, during the platform motions, the positions of the cables change. The set of all positions taken by one cable for all the poses of the platform in the CDRP workspace is called cable span [8]. The latter reference is the only previous work dealing with the issue of determining the cable span. It proposes a method to represent the cable span by a volume object but it does not deal with the issue of using this volume to check the absence of collisions.

While the problem of cable-cable interferences as well as cable-platform and cable-object collisions has been addressed several times in the literature, e.g. [9–13], to the best of our knowledge, the problem of avoiding collisions between a cable and the mobile part(s) of a device located on-board the CDRP platform

has never been treated yet. Hence, the contribution of this paper is a method to check the absence of such collisions within a box-shaped workspace of a CDPR. In order to accelerate computations related to collision avoidance checking, this method is based on an original bounding volume approximation of the cable span which is simpler than the one discussed in [8]. Moreover, this cable span approximation is calculated with respect to the mobile platform frame to enable simple testing of collisions with on-board devices.

This paper is organized as follows. The cable span of a CDPR is defined in Section 2. Based on the approximation of the cable span introduced in [8], two algorithms are discussed in Section 3 to test the eventuality of a collision between a cable and an object located on-board the mobile platform. A new and simpler bounding volume approximation of the cable span is proposed in Section 4. The characterization of the faces of this bounding volume and the corresponding collision avoidance testing are finally presented in Section 5.

2 Definition of the cable span

The frame attached to the CDPR mobile platform is denoted $\mathcal{F}_p$ and the fixed base frame is denoted $\mathcal{F}_0$. A vector $\mathbf{v}$ expressed in frame $\mathcal{F}_0$ is denoted by ${}^0\mathbf{v}$ and in $\mathcal{F}_p$ by ${}^p\mathbf{v}$. The pose of the platform is given by the vector $\mathbf{x}$, composed of its position vector $\mathbf{p}$ in $\mathcal{F}_0$ and of a vector $\boldsymbol{\theta}_p$ of three Euler angles defining the orientation of $\mathcal{F}_p$ in $\mathcal{F}_0$. Let $\mathbf{R}(\boldsymbol{\theta}_p)$ be the rotation matrix describing the orientation of the platform in $\mathcal{F}_0$. Each cable is considered to be a straight line segment between its base drawing point A_i and its platform fixing point B_i . These notations are shown in Figure 3.

The vector along the straight line segment of cable i , denoted $\mathbf{u}_i$, is given in frame $\mathcal{F}_0$ by:

$${}^0\mathbf{u}_i = {}^0\mathbf{p} + \mathbf{R}(\boldsymbol{\theta}_p){}^p\mathbf{b}_i - {}^0\mathbf{a}_i \quad (1)$$

The interval that contains all values of a scalar variable e is denoted $[\underline{e}, \bar{e}]$, with $\underline{e}$ the minimal value of e (lower bound) and $\bar{e}$ its maximal value (upper bound). The concatenation operator is written $||$. In this paper, the prescribed workspace $\mathcal{W}$ of a 6-DOF CDPR is defined as follows:

$$\mathcal{W} = \{ \mathbf{x} = \{ {}^0\mathbf{p}, \boldsymbol{\theta}_p \} \mid \{ {}^0\mathbf{p} \in [\underline{x}, \bar{x}] \times [\underline{y}, \bar{y}] \times [\underline{z}, \bar{z}] \} \\ || \{ \boldsymbol{\theta}_p \in [\underline{\alpha}_p, \bar{\alpha}_p] \times [\underline{\beta}_p, \bar{\beta}_p] \times [\underline{\gamma}_p, \bar{\gamma}_p] \} \} \quad (2)$$

It is a box-shaped workspace in the sense that, for a given orientation $\boldsymbol{\theta}_p$, the set of positions lying inside $\mathcal{W}$ is a box. In the remainder of this paper, it is assumed that $\mathcal{W}$ is fully included in the wrench-feasible workspace [14, 15] and, hence, that all poses in $\mathcal{W}$ can be reached with feasible cable tensions.

The cable span of cable i with respect to $\mathcal{F}_0$ is defined as $\mathcal{CS}_i^0 = \{ {}^0\mathbf{u}_i \mid \mathbf{x} \in \mathcal{W} \}$. Vector ${}^0\mathbf{u}_i$ is defined in (1) and according to the right-hand side of this equation and to (2), $\mathcal{CS}_i^0$ is the Minkowski sum of three sets:

- The box $[\underline{x}, \bar{x}] \times [\underline{y}, \bar{y}] \times [\underline{z}, \bar{z}]$ (position vectors ${}^0\mathbf{p}$)

Fig. 3: Schematic of the CoGiRo CDPR

- The portion of a sphere $\{\mathbf{R}(\boldsymbol{\theta}_p)^p \mathbf{b}_i \mid \boldsymbol{\theta}_p \in [\underline{\alpha}_p, \overline{\alpha}_p] \times [\underline{\beta}_p, \overline{\beta}_p] \times [\underline{\gamma}_p, \overline{\gamma}_p]\}$
- The point A_i having as position vector ${}^0 \mathbf{a}_i$

Note that ${}^p \mathbf{b}_i$ and ${}^0 \mathbf{a}_i$ are constant vectors. Hence, when the Euler angle set $[\underline{\alpha}_p, \overline{\alpha}_p] \times [\underline{\beta}_p, \overline{\beta}_p] \times [\underline{\gamma}_p, \overline{\gamma}_p]$ is not reduced to a single value, the cable span is a relatively complex geometric object (not necessarily convex) even for the simple definition of the workspace $\mathcal{W}$ given in (2). In [8], based on a discretization of the CDPR workspace and for a fixed orientation of the mobile platform, the cable span is approximated as a so-called generalized cone (a kind of cone whose cross section is a polygon not necessarily convex).

With the aim of checking the absence of collisions between a cable and the mobile part(s) of a device located on-board the mobile platform of a CDPR, the present paper deals with the cable span calculated with respect to the mobile platform frame $\mathcal{F}_p$. For cable i , this cable span is defined as $\mathcal{CS}_i^p = \{-{}^p \mathbf{u}_i \mid \mathbf{x} \in \mathcal{W}\}$ where:

$$-{}^p \mathbf{u}_i = \mathbf{R}(\boldsymbol{\theta}_p)^\top ({}^0 \mathbf{a}_i - {}^0 \mathbf{p}) - {}^p \mathbf{b}_i \quad (3)$$

Equation (3) is directly obtained from (1) by multiplying both sides by $\mathbf{R}(\boldsymbol{\theta}_p)^\top$. $\mathcal{CS}_i^p$ is thus the translation of the set $\{\mathbf{R}(\boldsymbol{\theta}_p)^\top ({}^0 \mathbf{a}_i - {}^0 \mathbf{p}) \mid \mathbf{x} \in \mathcal{W}\}$ by vector ${}^p \mathbf{b}_i$. This set corresponds to the volume swept by the box $\{{}^0 \mathbf{a}_i - {}^0 \mathbf{p} \mid {}^0 \mathbf{p} \in [\underline{x}, \overline{x}] \times [\underline{y}, \overline{y}] \times [\underline{z}, \overline{z}]\}$ when this box is rotated by $\mathbf{R}(\boldsymbol{\theta}_p)$ for all $\boldsymbol{\theta}_p$ in $[\underline{\alpha}_p, \overline{\alpha}_p] \times [\underline{\beta}_p, \overline{\beta}_p] \times [\underline{\gamma}_p, \overline{\gamma}_p]$. Similarly to the case of the cable span $\mathcal{CS}_i^0$ calculated in $\mathcal{F}_0$, the cable span $\mathcal{CS}_i^p$ is thus a relatively complex three-dimensional geometric object which is not necessarily convex.

Fig. 4: Convex polyhedral cone containing the cable span

3 Collision avoidance checking

In [8], based on a discretization of the CDPR workspace $\mathcal{W}$, the cable span $\mathcal{CS}_i^0$ is approximated as a so-called generalized cone. The same method could be applied to the cable span $\mathcal{CS}_i^p$. This generalized cone approximation is not necessarily convex (see Figure 3 in [8]) and may contain a large number of vertices depending on the number of points in the workspace discretization (and on the workspace definition). Therefore, it is not well suited for checking the absence of collision between a cable and mechanical parts on-board the mobile platform since this check consists in verifying that the volumes swept by the mechanical parts during their motions are fully outside of the cable span.

As an example, let us consider the convex polyhedral cone shown in Figure 4. Note that this cone is a simpler geometric object than the generalized cone considered in [8]. Let us also consider the simple case of testing whether or not a point Q is located inside this convex polyhedral cone. Several algorithms can be used to determine if Q is inside the cone, two of them are now briefly described.

First, a point-in-polygon approach, whose principle is illustrated in Figure 4, performs the following steps:

1. Obtain Q' the projection of Q on the axis of the cone. This defines a ratio k of, on the one hand, the distance between the base of the cone and Q' and, on the other hand, the length of the cone axis.
2. Apply the ratio k to the distances between the vertices of the base of the cone, which is a polygon, and the center of this polygon. The new polygon hereby obtained called $\mathcal{P}'$ is the section of the cone containing the point Q' .
3. Test whether or not Q belongs to the polygon $\mathcal{P}'$.

The third step can be implemented with a ray crossing algorithm [16] (which can also be used for non-convex polygons) whose complexity is $\mathcal{O}(n)$, n being the number of vertices of the base polygon.

Another approach consists first in determining the faces of the convex polyhedral cone. These faces may be given by the convex hull procedure or they can

be determined within the *polar sorting* phase of the generalized cone determination as detailed in [8]. Then, point Q is located inside the polyhedral cone if and only if it is located on the same side of each of the planes containing the cone faces. This second approach complexity is also $\mathcal{O}(n)$ where n is the number of vertices (or edges) of the base polygon.

The number of vertices n depends on the number of points used to discretize the CDPR prescribed workspace. Hence, the computational time needed to test if a given set is not interfering with the cable span, i.e. to check the absence of collision, depends on n . Moreover, the check must be done N times, N being the number of cables. Hence, using one of the two algorithms described above within an iterative optimization process slows down the whole procedure when n is (relatively) large. Using a simple, yet not overly conservative, bounding volume approximation of the cable span is thus important to enhance computational efficiency.

4 A simple bounding volume approximation of the cable span

Based on a discretization of the CDPR workspace $\mathcal{W}$, a simple bounding volume of the cable span $\mathcal{CS}_i^p$ (cable span in $\mathcal{F}_p$) can be obtained as follows.

Cable i is considered as a straight line segment between points A_i and B_i . In the mobile platform frame $\mathcal{F}_p$, the position of B_i is constant whereas the position vector of point A_i is $\mathbf{R}(\boldsymbol{\theta}_p)^\top ({}^0\mathbf{a}_i - {}^0\mathbf{p})$ and thus it depends on the mobile platform pose $\mathbf{x} = \{{}^0\mathbf{p}, \boldsymbol{\theta}_p\} \in \mathcal{W}$. In $\mathcal{F}_p$, the discretization of $\mathcal{W}$ generates a set of positions of point A_i and taking the convex hull of all these points produces a convex polyhedron. If the discretization is fine enough, this convex polyhedron is a good approximation of all possible positions of A_i in $\mathcal{F}_p$ when $\mathbf{x} \in \mathcal{W}$. However, as discussed in Section 3, the number of vertices of the bounding volume of the cable span should be kept small. Hence, instead of the convex hull, the smallest box $\mathcal{B}$ (aligned with the axes of $\mathcal{F}_p$) containing all positions of point A_i for $\mathbf{x}$ in the discretized workspace $\mathcal{W}$ is calculated. To this end, it suffices to determine, along each of the three coordinate axes of $\mathcal{F}_p$, the minimum and maximum coordinates of this set of positions of A_i .

The box $\mathcal{B}$ encloses all positions of points A_i in $\mathcal{F}_p$ for $\mathbf{x}$ in the discretized workspace $\mathcal{W}$, as illustrated in Figure 5. Hence, the polyhedron $\mathcal{P}$ obtained by connecting the fixed point B_i to $\mathcal{B}$ is a bounding volume approximation of the cable span $\mathcal{CS}_i^p$, i.e., a bounding volume of all the positions of the cable segment A_iB_i for $\mathbf{x}$ in the discretized workspace $\mathcal{W}$. In the remainder of this paper, it is assumed that the discretization of the workspace is such that this polyhedron $\mathcal{P}$ encloses the cable span $\mathcal{CS}_i^p$.

An example of such a polyhedron $\mathcal{P}$ forming a bounding volume approximation of the cable span is shown in Figure 6. As can be seen in this figure, $\mathcal{P}$ consists of the union of the box $\mathcal{B}$ and of a pyramid (convex polyhedral cone) having the fixed point B_i as apex. The base of this pyramid is a convex polygon whose vertices are some of the vertices of the box $\mathcal{B}$.

5 Collision avoidance checking with the new cable span bounding volume approximation

In Section 4, a polyhedron $\mathcal{P}$ forming a bounding volume approximation of the cable span $\mathcal{CS}_i^P$ has been introduced. A method to ensure collision avoidance between a cable and a moving device on-board the CDPR mobile platform consists in testing if the set of all possible positions of this device does not intersect $\mathcal{P}$. Indeed, $\mathcal{P}$ being a bounding volume of the cable span $\mathcal{CS}_i^P$, no intersection with $\mathcal{P}$ means no intersection with the cable span and thus no possible collision with the cable in the workspace $\mathcal{W}$. In order to test if a point or a set is outside polyhedron $\mathcal{P}$, the determination of the polyhedron faces is useful. Indeed, the polyhedron can be defined as the intersection of halfspaces bounded by the planes containing the faces (mathematically, a system of linear inequalities). Then, a point or a set is outside the polyhedron if and only if it is outside of at least one of these halfspaces (it violates at least one of the inequalities). The method to determine the faces of the polyhedron $\mathcal{P}$ forming a bounding volume approximation of the cable span is described below.

As mentioned at the end of Section 4, the polyhedron $\mathcal{P}$ is the union of the box $\mathcal{B}$ and of a pyramid, the apex of the pyramid being the fixed point B_i (Fig. 6). The number of faces of this polyhedron depends on the number of faces of the box $\mathcal{B}$ that are visible from point B_i . Three cases must be distinguished.

- One face of $\mathcal{B}$ is visible from B_i : As shown in Figure 7, $\mathcal{P}$ consists of nine faces. Four of these faces are triangles which form the pyramid. Point B_i , the apex of the pyramid, is a vertex common to these four faces. The five other faces of $\mathcal{P}$ are the faces of the box $\mathcal{B}$ that are not visible from B_i .
- Two faces of $\mathcal{B}$ are visible from B_i : As shown in Figure 8, $\mathcal{P}$ consists of ten faces. Six of these faces form the pyramid with point B_i as a common vertex. The four other faces of $\mathcal{P}$ are the faces of $\mathcal{B}$ that are not visible from B_i .

Fig. 7: Faces of the polyhedron $\mathcal{P}$ if one face of $\mathcal{B}$ is visible from B_i

Fig. 8: Faces of the polyhedron $\mathcal{P}$ if two faces of $\mathcal{B}$ are visible from B_i

Fig. 9: Faces of the polyhedron $\mathcal{P}$ if three faces of $\mathcal{B}$ are visible from B_i

- Three faces of $\mathcal{B}$ are visible from B_i : As shown in Figure 9, $\mathcal{P}$ consists of nine faces. Six of these faces form the pyramid with point B_i as common vertex. The three other faces of $\mathcal{P}$ are the faces of $\mathcal{B}$ that are not visible from B_i .

In addition to these three cases, particular cases must be dealt with. These particular cases appear when point B_i lies in one or several planes containing the faces of the box $\mathcal{B}$. For simplicity, these particular cases are not detailed in this paper. They do not cause any particular difficulty.

Based on this characterization of the faces of the polyhedron $\mathcal{P}$, the mathematical description of each of these faces is straightforward. Let us consider face k of $\mathcal{P}$. Its mathematical description consists in a point P_k lying on the face and a vector $\mathbf{n}_k$ normal to the face and pointing to the outside of $\mathcal{P}$. Point P_k and vector $\mathbf{n}_k$ define the plane containing face k . A point Q is then outside of the polyhedron if and only if, for at least one face k , it is not on the same side of this plane than $\mathcal{P}$, i.e., if and only if there exists k such that $\overrightarrow{P_k Q} \cdot \mathbf{n}_k > 0$.

In the case of a face k of $\mathcal{P}$ which is also a face of the box $\mathcal{B}$ (a rectangle), point P_k can for instance be one vertex of the rectangle or its center and vector $\mathbf{n}_k$ is taken along the normal to this rectangle pointing to the outside of $\mathcal{B}$. In the case of a face of the pyramid having point B_i as apex, the face is a triangle whose three vertices are known so that point P_k and vector $\mathbf{n}_k$ are also straightforward to define. Note that the determination of the faces of $\mathcal{P}$ and the calculation of their mathematical descriptions (P_k and $\mathbf{n}_k$) can be done offline, i.e., before any use of $\mathcal{P}$ to test the absence of collision between a cable and a device on-board the CDPR mobile platform. Typically, within an iterative optimization

Fig. 10: All the bounding volumes of the cable spans of the CDPR *CoGiRo* as seen in the platform frame $\mathcal{F}_p$

process, only dot products $(\overrightarrow{P_k Q} \cdot \mathbf{n}_k)$ need to be calculated. Consequently, the computation cost of testing collision avoidance with the cables across the CDPR workspace is small.

Figure 10 show the polyhedra $\mathcal{P}$ which are bounding volume of the cable spans of the eight cables of the CDPR *CoGiRo* for a given workspace $\mathcal{W}$. As can be seen, the cable span bounding volumes represent a significant part of the space around the platform and, in fact, surround the platform. This is mostly due to the cable arrangement of *CoGiRo* [7]. This CDPR being suspended, it can also be observed that the space below the platform is free.

6 Conclusion

This paper dealt with the problem of verifying the absence of collisions between the cables of a CDPR and mobile devices located on-board the mobile platform, across a prescribed workspace. The cable span is defined as the set of all positions taken by one cable of the CDPR for all the poses of the mobile platform in the prescribed workspace. In this paper, the cable span as seen in the platform coordinate frame is considered. If the set of all possible motions of a device on-board the mobile platform is fully outside of the cable span, then no collision between the device and the cable can occur within the prescribed workspace. However, the cable span being a relatively complex geometric object, a bounding volume approximation of the cable span has been proposed in this paper. This bounding volume is a polyhedron and the characterization of the faces of this polyhedron has been given. Using this polyhedron as a bounding volume of the cable span allows to accelerate computations related to collision avoidance checking.
